CHAPTER 19 ■ HEAD TRAUMA

RANDALL M. CHESNUT

KEY POINTS

- 1 Traumatic brain injury (TBI) results from both primary (impact disruption of brain and vascular tissue) and secondary (hypoxia, hypotension, pyrexia, effects of elevated intracranial pressure [ICP] and biochemical processes) insults.
- 2 Secondary insults are often the determining factor in outcome and, unlike primary injury, are amenable to medical intervention and, thus, are generally the focus of care.
- 3 Increases in ICP are deleterious because of herniation or ischemia (due to decreased cerebral blood flow), and the first-order attempt to avoid ischemia should be maintaining the cerebral perfusion pressure at greater than 60 mm Hg.
- 4 Assessment of the head-injured patient requires evaluation of (a) level of consciousness (using the Glasgow Coma Scale); (b) pupil asymmetry, dilation, or loss of light reflex; and (c) best motor response to painful stimulus.
- 5 Computed tomography is the diagnostic test of preference and should be used serially in settings of increased risk of progression of TBI.
- 6 Initial increases in ICP are treated by removal of mass lesions (blood collections or edematous injured brain), cerebrospinal fluid drainage, mild hyperventilation (PaCO_2 30 to 35 mm Hg), or hyperosmolar therapy using mannitol or hypertonic saline to decrease edema. Hyperventilation should be avoided early (PaCO_2 35 to 38 mm Hg) and used cautiously (PaCO_2 30 to 35 mm Hg) later to treat unresponsive elevated ICP.
- 7 Refractory ICP elevation may be treated medically with more aggressive hyperventilation (PaCO_2 <30 mm Hg), barbiturates, or hypothermia, generally guided by aggressive, multimodality monitoring. Decompressive craniectomy constitutes an effective surgical treatment for refractory intracranial hypertension.

EPIDEMIOLOGY

In the field of trauma, other than for exsanguinating injuries, brain trauma is the injury most commonly responsible for mortality, accounting for about half of deaths at the scene. The injuries are generally blunt, occurring most frequently in motor vehicle crashes (MVCs). As many as two thirds of all MVC victims sustain some degree of brain injury. Complications from closed head injuries are the single largest cause of morbidity and mortality in patients who reach the hospital alive. Of patients who require long-term rehabilitation, head trauma is usually the primary injury.

These data are generally applicable to children as well. Although the mechanisms vary, head injuries are the major cause of morbidity and mortality in childhood trauma victims, accounting for an annual mortality rate of 1 per 1,000 in this age group.

Recently, with the aging of the population, a new spectrum of brain injury is blossoming, consisting of persons aged 60 years or older whose primary mechanism of injury is a fall. These patients have less inherent neurologic plasticity, limiting their recovery potential. As well, they often have significant comorbidities and may be on one or more anticoagulants. Management of these patients often takes a course differing from that optimal for the younger population.

In the mid-1990s, gunshot wounds surpassed other mechanisms as the most common cause of brain injuries.¹ Because of a case mortality ratio of approximately 94%, however, they continue to represent only a fraction of the brain injuries that come to definitive hospital care. In addition, because civilian gunshot wounds to the head are frequently isolated injuries, their spectrum of care varies more toward individual neurosurgical management.

PATHOPHYSIOLOGY

- 1 Traumatic injury to the brain involves a primary brain injury that occurs at impact and leads to disruption of brain sub-

stance and blood vessels. In addition, secondary brain injury may result from hypoxia, hypotension, pyrexia, the effects of increased intracranial pressure (ICP), and altered cellular biochemical processes that are often ongoing long after the primary insult.

Primary Injury

Energy transfer to the head causes direct disruption of neurons, glia cells, and microvasculature localized at the area of impact. As the brain rebounds within the skull, it is also vulnerable to impact with the opposite inner table. Therefore, coup/contrecoup injury to the contralateral brain is relatively common, in some cases being the more severe site of damage.

Particularly when the mechanism includes rotational forces, head trauma can result in widespread disruption of white matter axons throughout the brain, producing the condition termed *diffuse axonal injury* (DAI). Such injuries often damage a large number of widely distributed neurologic systems. When such injuries involve ascending pathways in both hemispheres or in the brainstem, the result is a depressed level of consciousness. The brain is also subject to torsion injury resulting from rotation around the fixed brainstem. This type of injury can damage the reticular activating system, producing unconsciousness.

Intracranial hemorrhage can take many forms. Direct laceration of epidural arteries from impact fractures or bleeding from fracture lines produces epidural hematomas, which damage the brain by compression. Disruption of bridging subdural veins and bleeding from cortical tissue damage produces a subdural hematoma, which is generally associated with disruption of underlying brain tissue. Intracerebral contusions, lacerations, and hematomas are caused by direct tissue disruption with associated vascular injury, producing neuronal damage and intraparenchymal bleeding.

Penetrating injury damages the brain through tissue injury caused directly by the projectile and, in the case of projectiles

with relatively high velocity, result in disruption of neural tissue at a greater distance from the track via cavitation injury. In survivors, the extent and degree of the cavitation injury (related linearly to the mass and in a squared fashion to the velocity of the projectile) are often the primary determinant of outcome. Another source of morbidity is vascular injury, producing aneurysms, pseudoaneurysms, and other vascular anomalies that may present immediately or be delayed.

Whether a projectile or direct impact causes contusion, subdural hematoma, epidural hematoma, or diffuse axonal injury, little can be done therapeutically to change the magnitude or location of the primary injury once it has occurred. As such, most of our present care focus is on secondary injuries.

Secondary Injury

Secondary brain injuries result from events occurring after the primary insult, either from the direct consequences of the process initiated by the primary injury or from deleterious exogenous influences. The occurrence and magnitude of secondary insults are often the determining factor in outcome from brain injury. In contrast to primary injuries, secondary insults are amenable to medical management and even prevention; they are the focus toward which the medical treatment of brain injury is primarily directed.

Primary tissue injury initiates a variety of biochemical processes, including free radical-mediated lipid peroxidation, excitotoxic “super-activation” of glutamate-aspartate neurotransmitter systems, and alterations in membrane receptor and ionic channel characteristics, among others. A variety of genomic processes are also activated, including apoptotic cell death, which is a focus of much current research. These processes can proceed for significant periods of time following primary injury and often are self-sustaining. The goal of the numerous clinical trials involving treatment of patients with brain trauma with various pharmacologic agents is to determine the means by which these processes may be attenuated or reversed. Unfortunately, to date, no clinically useful tools have been obtained from such research.

The primary external secondary injury processes occurring following brain injury are hypotension and hypoxia. Hypotension is the number one treatable determinant of severe head injury. A single episode of systolic blood pressure less than 90 mm Hg occurring during the period from injury through resuscitation doubles the mortality and significantly increases the morbidity of any given brain injury.² Furthermore, an early hypotensive episode strongly increases the probability of later intracranial hypertension. For these reasons, rapid and complete restoration of blood pressure is the most important goal in the resuscitation of the brain-injured patient. The old saw of “keeping the brain injury patient dry” by restricting fluids has been found to be completely erroneous and has been abandoned. Also for this reason, the somewhat unconventional suggestion of using pressors as temporizing agents during volume resuscitation has been incorporated into brain injury care.²

Hypoxia (apnea or cyanosis in the field or a partial pressure of arterial oxygen [PaO_2] <60 mm Hg) is also an independent predictor of poor outcome.^{2,3} The frequency and magnitude of hypoxia have been notably decreased by modern airway management techniques, particularly early endotracheal intubation and assisted ventilation, in addition to ensuring adequate oxygen-carrying capacity through the avoidance of anemia.

Another important source of secondary injury is pyrexia. Fever is correlated with poorer outcome both by degree and duration.³ Although the precise mechanism of this effect remains unclear, increased metabolism and the resultant metabolic recruitment of additional blood flow (and blood volume) is presumed to play a role.

Intracranial Pressure. ICP is a function of the aggregate volumes of brain, cerebrospinal fluid (CSF), and blood within the fixed intracranial compartment. Mild or slow expansion of one or two of these compartments can be buffered by compensatory decreases in either the CSF or blood compartments (into the spinal subarachnoid space or the venous sinuses, respectively). When this buffering capacity is exceeded, the compliance of the brain is compromised and small additional increases in any intracranial compartmental volume will produce marked elevations in ICP.

Intracranial hypertension is considered deleterious via two somewhat separable mechanisms: herniation and ischemia. Herniation occurs when a pressure gradient exists across an incomplete barrier, such as the tentorium, falx cerebri, or foramen magnum. It is deleterious because of the tissue damage that occurs and direct compression of adjacent vessels. Transtentorial herniation, the most recognized form, is manifest by anisocoria, motor posturing, autonomic disturbances, and death. The specter of herniation is the major determinant of the absolute threshold of ICP management, which is generally accepted as 20 to 25 mm Hg (although this range has not been well determined empirically). A major unanswered question is how ICP should be managed when separated from perfusion, both in terms of measuring the probability of herniation and in determining whether there are detrimental effects of elevated pressure per se. It is hoped that ongoing research in the area of cerebral compliance will produce clinically useful information regarding these issues.

The second deleterious aspect of intracranial hypertension is elevated resistance to cerebral blood flow (CBF), resulting in or exacerbating ischemia. This resistance can be very roughly approximated by cerebral perfusion pressure (CPP), which is defined as the difference between mean arterial blood pressure and ICP:

$$\text{CPP} = \text{mean arterial pressure} - \text{ICP}$$

Under normal circumstances, cerebral pressure autoregulation maintains CBF stable over a wide range of CPP (approximately 50 to 150 mm Hg) (Fig. 19.1). Following injury to the brain, this autoregulation is generally disrupted. This disruption can be complete, resulting in a pressure-passive system.⁴ More frequently, the disruption is incomplete, characterized by a normal sigmoid shape but with abnormal elevation of the lower breakpoint above the normal value of 50 mm Hg (sigmoid dashed line). A probable consequence of this disruption is that a CPP that is satisfactory for uninjured patients may be associated with a lower CBF following head trauma (range of hypoperfusion).

In a pressure-passive system, cerebral blood volume (CBV) will increase in proportion to CPP. In such an instance, the goal is to keep the CPP just above the level of cerebral ischemia, thereby minimizing iatrogenic intracranial hypertension driven by increased CBV. In the situation of incomplete disruption, the goal is to keep CPP within the range of autoregulation, because this not only avoids ischemia but also may decrease ICP if autoregulatory vasoconstriction in response to increased CPP serves to decrease CBV.

Confounding this situation are reports that CBF may be disproportionately depressed during the early postinjury period. It is particularly critical, therefore, that CPP be supported assiduously from the first point of patient contact. Because hyperventilation causes vasoconstriction, thereby decreasing CBF, the use of hyperventilation during this early period is somewhat more hazardous than after the first 24 to 48 hours.

The preceding physiologic reasoning supported the increase in use of cerebral perfusion pressure therapy, wherein CPP was elevated to 70 mm Hg or higher throughout the course of intracranial hypertension. The efficacy of CPP therapy has been suggested by studies without internal controls reporting decreased morbidity and mortality associated with CPP therapy

FIGURE 19.1. Cerebral pressure autoregulation. The normal relationship is indicated by the *solid line* with autoregulatory breakpoints at 50 and 150 mm Hg. Two disrupted states are also diagrammed. Complete loss of autoregulation (*straight dashed line B*) results in a pressure-passive system wherein cerebral blood flow (CBF) (and cerebral blood volume [CBV]) increases linearly with cerebral perfusion pressure (CPP). The more common form of disruption is indicated by the sigmoid (*dashed line A*) where the major alteration is a right shift in the lower breakpoint. The *circles* at the top of the figure represent the diameters of the resistance vessels in the normal situation. The area of the circles represents CBV. Shifting this relationship to the right by 30 mm Hg would represent the partially disrupted state. (© R.M. Chesnut, MD., reproduced with permission.)

as compared to historical controls that practiced more conventional ICP-based therapy. The result of such reports was that CPP-based therapy at significantly elevated values became widely accepted as standard practice.

Subsequent reports, however, suggested that such acceptance might have been premature. Potential errors in selecting the historical control groups against which CPP-based therapy results were compared have prevented differentiating the effects of artificially increasing CPP from those of simply avoiding in-hospital hypotensive episodes. When control groups are selected to address this deficiency, it becomes apparent that CPP-based therapy may simply be a proxy for avoidance of transient ischemia.⁵ Such a possibility is further supported by analysis of data from the National Institutes of Health (NIH)-funded North American Brain Injury Study on Hypothermia, which suggested that dips of CPP below 60 mm Hg are much more highly correlated with outcome than the efficacy of maintaining CPP above 70 mm Hg.⁶ In addition, it appears that elevating CPP may increase the duration of intracranial hypertension.^{7,8} This might be caused by the elevation of hydrostatic forces favoring the formation of vasogenic edema, thereby iatrogenically prolonging brain swelling and ICP elevation. Finally, the results of a prospective randomized investigation of CPP-based versus ICP-based management suggest that there is no overall difference in outcome between the two strategies, with the major effect of CPP-based therapy being the alteration in the mode of exitus from early, ICP-related deaths to delayed mortality from systemic complications (especially acute respiratory distress syndrome [ARDS]).⁹ Such considerations imply that, although attention to CPP (and, thus, cerebral perfusion) is important, the proper method of managing CPP remains to be determined. It is clear, however, that routinely elevating CPP to values above 70 mm Hg is not associated with improved outcome.¹⁰ This is reflected in the most recent revision of the Guidelines for the Management of Severe Brain Injury wherein the recommended CPP threshold has been decreased to 60 mm Hg based on an updated evidence review.¹¹

Ultimately, the goal of managing blood pressure and CBF is to maintain a level of perfusion that meets the metabolic demands of the cell. The major problem with managing traumatic brain injury (TBI) based on pressure measurements is that alterations in cerebral metabolism will be missed. This may be of significant importance because the usual course of

cerebral metabolism is to decrease following injury, slowly returning toward normal in patients who improve. One implication of such a metabolic course is that CBF values that would be dangerous under normal metabolic conditions might be satisfactory when cerebral metabolism is depressed. Indeed, because metabolic flow autoregulation is generally preserved following TBI, low values of CBF might often reflect flow:metabolism matching. One result of such a course of metabolic change might be that CPP elevation is reasonable during the early (i.e., first 12 to 24 hours) posttraumatic period when metabolism is near normal and ischemia is both probable and extremely devastating. Subsequently, when metabolism falls, CPP elevation may not be necessary and, indeed, may be counterproductive.

Absolute metabolic information is not readily available in the clinical situation. The relative balance between metabolic needs and substrate delivery, however, can often be usefully estimated by monitoring the oxygen saturation in the internal jugular vein (JVS_O₂) or the tissue oxygen tension in the brain (P_tO₂). Although limited by problems of averaging, incomplete sampling of the total cerebral tissue volume, and technical issues of accuracy, the monitoring of JVS_O₂ is a clinically useful method of detecting some otherwise occult episodes of ischemia as well as tailoring therapy to individual patient needs as they evolve.¹² By adding measurement of the arteriojugular lactate difference (AVDL), some occult areas of ischemia or anaerobic metabolism can also be detected that would not be apparent if only JVS_O₂ were measured.

More recently, it has become possible to measure brain tissue oxygen tension (P_tiO₂) using implantable Clark electrodes. This makes it possible to follow the balance between oxygen consumption and delivery, thereby providing the potential of detecting actual ischemia. These electrodes are easily implanted, either in a tunneled fashion or through a threaded bolt. Although absolute thresholds have not been rigorously determined, values above 15 to 20 mm Hg are generally considered adequate and values below 5 mm Hg are associated with increasingly poor outcome in a duration-dependent fashion.^{13,14} The major limitations of this system are the extremely focal nature of this monitoring and technical issues with reliability. Although there is theoretical attractiveness to monitoring at the border of focal injuries (the “penumbra”), most monitoring is performed within normal brain.

We have found that combining the monitoring of ICP, CPP, JVS_O₂, AVDL, PtiO₂, and quantitative regional CBF (with cold xenon computed tomography [CT] or CT perfusion CBF studies) has allowed us to safely tailor management to cerebral needs, thereby avoiding overtreatment and undertreatment, minimizing the likelihood of iatrogenic systemic toxicity, and shortening intensive care unit (ICU) stay. Most “straightforward” cases of brain injury, where ICP control is not difficult and systemic determinants of perfusion are stable and adequate, do not require invasive multimodality monitoring. In the approximately 10% of cases where these parameters are problematic, however, expanded monitoring is strongly suggested. Given the toxicity of many of the treatments used for ICP management and their often unfavorable interactions with therapies that may be indicated for other systemic abnormalities (e.g., ARDS), it is important to avoid overtreatment of TBI patients by targeting interventions at demonstrated pathologies.

Treatment of systemic hypertension is rarely indicated in the patient with head injury. There is no evidence that hypertension promotes continued intracranial hemorrhage, and hypertension related to brain injury generally resolves when the intracranial hypertension is controlled. When profound hypertension requires treatment, short-acting, selective beta-blockers or intravenous (IV) titration of calcium channel blockers should be used. Vasodilators (e.g., sodium nitropruside) should be avoided because they increase CBV, which can exacerbate ICP.

As noted, metabolic autoregulation is the other and somewhat more fundamental type of intrinsic CBF control. Vasoconstriction is nonlinearly proportional to pH and, therefore, subject to manipulation of partial pressure of arterial carbon dioxide (PaCO₂). As a result, hyperventilation-induced alkalosis produces vasoconstriction, resulting in a decrease of both CBF and CBV. Although the latter is beneficial in controlling ICP, the former is potentially deleterious and mandates caution when using hyperventilation. For reasons outlined earlier, hyperventilation is best avoided whenever possible during the early postinjury course when the risk of ischemia is extremely high. Also, because of rapid compensatory buffering of iatrogenic hypocapnic alkalosis, the beneficial effects of hyperventilation tend to be relatively short-lived.

Cerebral Edema and Osmolar Therapy

Cerebral edema during the early postinjury period is generally cytotoxic (intracellular). Later, vasogenic (extracellular) edema may also play a role in brain swelling. Although resulting from different mechanisms (cellular membrane dysfunction and blood–brain barrier breakdown), our present treatment for cerebral edema in trauma is limited to the administration of osmotic agents, most classically mannitol. Generalizing the documented efficacy of corticosteroids to decrease tumor-related cerebral edema to the setting of trauma-induced edema has proven to be ineffective and actually harmful and is now considered contraindicated.^{11,15}

Hyperosmolar agents increase the osmotic gradient, drawing fluid from the interstitial compartment into plasma, thereby reducing brain volume. In regions where the blood–brain barrier has been disrupted, however, such agents are minimally effective and can actually leak into tissues.¹⁶ Fortunately, the area of blood–brain barrier breakdown is generally much smaller than the area of edema that it creates so that hyperosmolar therapy is generally effective in lowering ICP. Nevertheless, caution should be exercised when there are large areas of suspected blood–brain barrier breakdown (such as in regions of infarction) where large-scale parenchymal sequestration of osmotic agents might exacerbate edema formation and increase local mass effect.

Mannitol also has other mechanisms of action. It creates an acute increase in intravascular volume, which may transiently

improve cardiac output and CBF. It also appears to cause acute and transient vasoconstriction as a result of its ability to decrease blood viscosity and improve flow. Both of these effects are of more immediate onset than the osmotic effects of mannitol. They may be responsible for its early effects on ICP and may also explain why mannitol is more effective in lowering ICP when administered as a bolus rather than a slow infusion.

Mannitol, however, can produce significant diuresis. The resulting hypovolemia can result in hypotension, not only producing secondary insult to the brain but also causing intracranial hypertension from autoregulatory vasodilatation. Recent evidence suggests that the apparent relationship between early mannitol use and hypotension may be associated with hypotensive episodes that are correlated with increased morbidity and mortality.¹⁷ Therefore, mannitol should be used only for proven or strongly suspected intracranial hypertension; it should be avoided under conditions of hypovolemia, and fluid losses should be diligently replaced. Because smaller doses of mannitol (0.25 g/kg) are nearly as efficacious as larger doses (1 g/kg) in lowering ICP, the smaller doses should be used whenever possible.

More recently, the use of hypertonic saline to elevate serum osmolality has become increasingly incorporated into TBI management. This approach has been studied best in the pediatric population, where it has been demonstrated to be beneficial in controlling intracranial hypertension (although not yet rigorously shown to improve clinical outcome). In those studies, 3% sodium chloride solution has generally been used, infused at 0.5 to 1.0 mL/kg per hour. As a result of such publications, the Guidelines for the Management of Severe Pediatric Brain Injury contained recommendations placing the use of hypertonic saline–based osmotherapy at the same level as the use of mannitol, leaving the choice to the physician.¹⁸

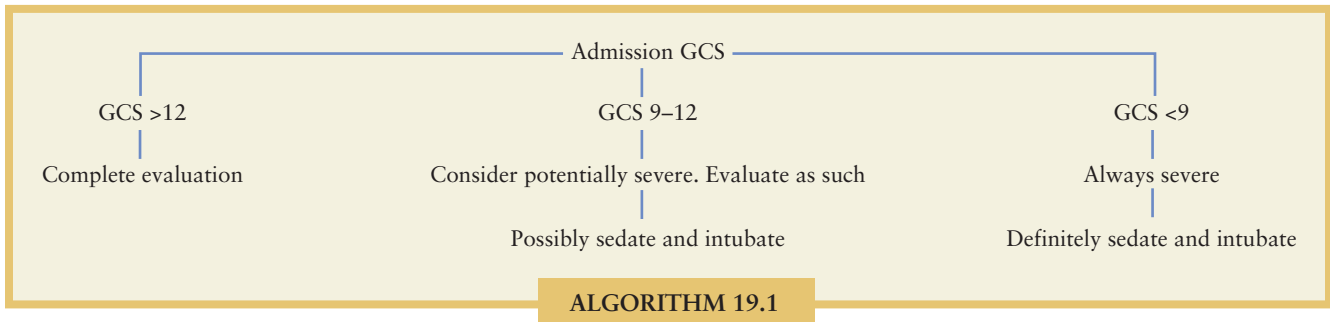

In the treatment of adult TBI, hypertonic saline has been widely incorporated into routine therapy, with concentrations ranging from 3% to 23% being used for continuous infusion or “bolus” injection. Unfortunately, at present, there is little solid evidence available to help clarify the optimal usage of hypertonic saline in TBI. In bolus form, it appears effective in acutely lowering ICP, but comparison data on its relative efficacy and duration with respect to mannitol are lacking. Also, rapid infusion of higher concentrations of hypertonic saline through a central line can produce temporary asystole. When used for continuous infusion, hypertonic saline is effective in raising serum osmolality while maintaining vascular volume and has widely replaced scheduled dosing of mannitol.

Regardless of whether mannitol or hypertonic saline is the agent used to raise the serum osmolality, when withdrawing therapy, the serum sodium and osmolality should be allowed to return to within normal limits prior to removing the ICP monitor. The risk of rebound intracranial hypertension associated with the administration of hypotonic solutions such as half-normal saline or lactated Ringer solution can thereby be minimized.

CLINICAL ASSESSMENT

The objectives during early clinical assessment of the patient with head injury are multiple and must be accomplished simultaneously. These include establishing adequate oxygenation, ventilation, and circulatory stability and evaluating the extent of brain injury while treating ICP elevations. Although some evidence indicates that systemic hypotension may infrequently be the result of a head injury, always initially presume that hypotension in a trauma patient is the result of hypovolemia. It is a significant error to withhold volume resuscitation in a misdirected effort to control cerebral edema.

During initial assessment, mental status changes cannot be presumed to be the result of drugs or alcohol, although routine toxicology screening is appropriate. It should be presumed

ALGORITHM 19.1. Glasgow Coma Scale (GCS) triage guide for initial evaluation of head injury. For the motor scale, the best response for any limb is recorded.

that any change in mental status or the neurologic examination in general, or any evidence of herniation (e.g., anisocoria), suggests an expanding intracranial mass lesion. Under such circumstances, therapeutic ICP reduction becomes the first priority and diagnostic imaging or surgical decompression must be accomplished emergently.

Do not assume that apparent neurologic unresponsiveness represents a lack of sensitivity to pain. Noxious stimuli, such as placement of urinary drainage catheters, nasogastric tubes, or IV catheters, can precipitate ICP peaks during resuscitation. These procedures should be done quickly and efficiently, optimally after sedation. Endotracheal intubation is particularly likely to induce herniation in borderline cases. Whenever practical, consider premedication with analgesics, sedatives, or IV or endotracheal lidocaine before airway instrumentation.

- 4 With regard to the brain injury, several critical assessments are necessary and should be precisely recorded because trends are at least as important as any single observation. The three key parameters are level of consciousness, pupillary reflexes and size, and the motor examination.

Glasgow Coma Scale

The single most important assessment for a patient with head injury is to evaluate the level of consciousness. In this regard, the Glasgow Coma Scale (GCS) has become an international standard that is easily, rapidly, and reliably obtained (Algorithm 19.1). Components of the GCS include assessment of eye opening, verbal response, and motor response. It is not, and was never intended to be, a neurologic examination and should not be substituted for such information.

It has been suggested that early estimations of GCS, done in the field by emergency personnel, are often inaccurate.¹⁹ In some areas, alternate, simpler systems (e.g., the AVPU scale) are accepted for this reason. The Guidelines for the Prehospital Care of Severe Brain Injury, however, support the continued use of the GCS for all prehospital care providers.²⁰ Special training has been developed by the Brain Trauma Foundation to optimize its accuracy (<http://www.braintrauma.org/>). The routine use of GCS provides a useful measure of initial injury severity and allows stratification for initial therapy as well as for outcome analysis.

For triage purposes, patients can be stratified using their GCS scores into those with severe injuries (GCS score <8), moderate injuries (GCS score 8 to 12), or mild injuries (GCS score >12; see Algorithm 19.1). Patients with severe head injuries require immediate endotracheal intubation, mechanical ventilation, and complete resuscitation; any clinical evidence of intracranial hypertension (e.g., signs of herniation) mandates maximal therapy to decrease ICP.

Many significant injuries occur in patients with GCS scores between 8 and 12. Although this is defined as the mod-

erate injury group, all these patients require maximal brain resuscitation until a definitive diagnosis can be made. A patient with a GCS score of 12 or more tends to be confused but responsive to verbal stimulation. These patients need serial neurologic evaluations because they are in the group that can “talk and die” because of missed or delayed intracranial pathology. In general, for any brain injury, however, and whenever expedient, attention to other major injuries can take relative priority over cerebral imaging or management, whenever necessary.

Pupils

Pupillary asymmetry, dilation, or loss of light reflex in an unconscious patient usually reflects herniation because of the mass effect from intracranial hemorrhage ipsilateral to the dilated pupil. The probability of an intracranial mass lesion can be roughly approximated given the degree of anisocoria (≥ 1 mm or ≥ 3 mm), the mechanism of injury (\pm motor vehicle crash), and age (Fig. 19.2).²¹ Occasionally, pupillary signs may indicate direct second or third nerve injury or trauma to the globe, but this must always be a diagnosis of exclusion. An unequal and nonreactive pupil is the cardinal sign that herniation is occurring, and rapid lowering of ICP is essential. An

FIGURE 19.2. Estimated percentage chance of an extra-axial intracranial mass lesion greater than 25 mL as a function of degree of anisocoria, age, and mechanism of injury. Mechanism of injury was defined as motor vehicle accident (MVA) or other mechanism (not MVA). (Reproduced with permission from Chesnut RM, Gauttill T, Blunt BA, et al. The localizing value of asymmetry in pupillary size in severe head injury: relation to lesion type and location. *Neurosurgery* 1994;34:840–845.)

ovoid pupil is also ominous and is associated with injuries that result in herniation in approximately 15% to 20% of patients.

Motor Examination

The motor system is examined for asymmetry, abnormal posturing, or lack of movement. Hemiparesis, paraparesis, or quadriparesis suggests a cervical or thoracolumbar spine fracture with spinal cord injury. Hemiparesis secondary to brainstem herniation from the mass effect may be either ipsilateral or contralateral to the side of the dilated pupil or an intracranial mass lesion.²¹ Hemiparesis may also result from significant brain contusion. In the unconscious patient, a painful stimulus should be used to evaluate motor function. All four extremities should be examined and the results noted, because only the response of the best limb will be reflected in the GCS score.

INITIAL TREATMENT

Evidence-based Medicine and the Management of Traumatic Brain Injury

The publication of the first edition of the Guidelines for the Management of Severe Brain Injury in 1996 represented a significant step in standardizing the management of TBI based on published, peer-reviewed literature.²² This document represents the application of a strict evidence-based process to 14 topics relevant to TBI care. Following an exhaustive, explicitly defined literature search covering each topic, the recovered literature was carefully classified along a three-point continuum of scientific rigor. As such, each article was ranked as class I, class II, or class III and the analysis of the scientific basis of each topic was predicated on the most scientifically rigorous (highest literature class) reports available. This process produced a set of standards, guidelines, and options for treatment where **standards** (based on class I evidence) represent principles with a high degree of clinical certainty, **guidelines** (based on class II evidence) reflect principles with a moderate degree of clinical certainty, and **options** (based on class III evidence) reflect principles for which unclear clinical certainty exists. By specifically defining the scientific foundation on TBI management issues, the Guidelines for the Management of Severe Brain Injury provided an unbiased reference focused on facilitating scientific management of TBI.

Since the initial publication of the Guidelines for the Management of Severe Brain Injury, it has undergone updating and revision^{10,11} encompassing more recently published data and revising earlier practice recommendations where indicated as well as expanding the scope of covered topics. The same evidence-based process has also been applied in the generation of other sets of brain injury guidelines. The Guidelines for the Prehospital Management of Traumatic Brain Injury were published in 2002,²⁰ spawning the training efforts mentioned previously. In 2001, the Guidelines for the Management of Penetrating Brain Injury were published.²³ The Guidelines for the Management of Pediatric Brain Injury were published in 2003.¹⁸ The Guidelines for the Surgical Management of Traumatic Brain Injury were published in 2001.²⁴ In light of the need for responsiveness of all evidence-based reports to the publication of new literature, the Brain Trauma Foundation has established a process to ensure that all of these reports are regularly updated and expanded through the Neurosurgical Evidence-based Medicine Center at the University of Washington.

Wherever applicable, the findings contained in these guidelines have been incorporated into this text. For details, the reader is referred to the source documents.

GUIDELINES FOR THE MANAGEMENT OF SEVERE HEAD INJURY

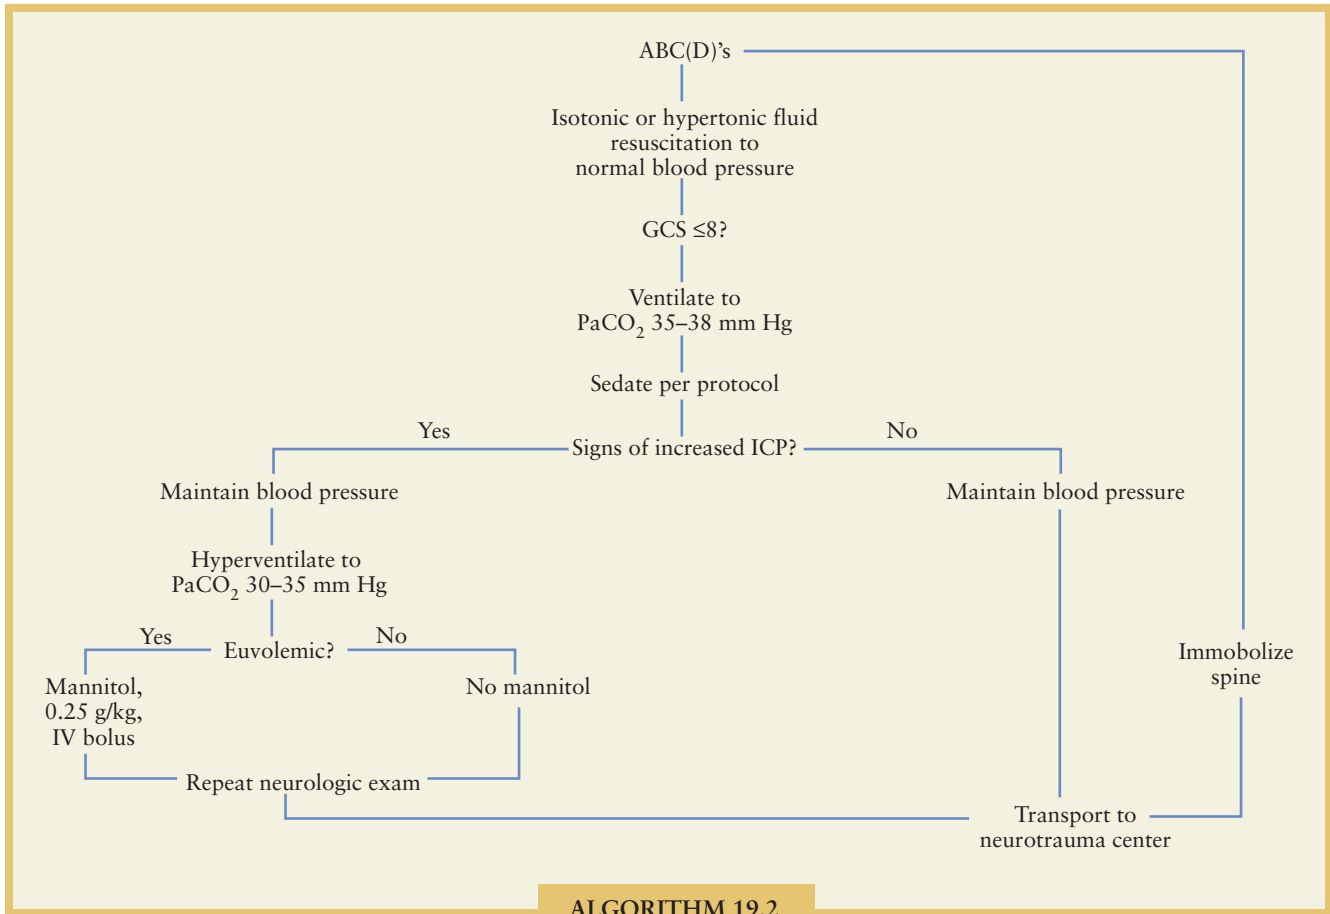

Although there is no present technology for its quantification before the insertion of an ICP monitoring device, early intracranial hypertension may certainly exert a detrimental influence on outcome. Not only do all treatment modalities for intracranial hypertension have serious potential complications, but also many of them can directly interfere with resuscitation procedures (e.g., use of diuretics). The efficacy of successful systemic resuscitation in improving the likelihood of survival from trauma in general is well accepted. In addition, the acknowledged negative influence of secondary insults (e.g., hypotension and hypoxia) on outcome from severe head injury renders systemic resuscitation a *condicio sine qua non*, which provides a vital infrastructure on which treatment of intracranial hypertension must be based. Therefore, all treatment must be consistent with optimal systemic resuscitation. When definite signs of transtentorial herniation occur, they should be interpreted as definitive evidence of intracranial hypertension and prompt, rapid, and definitive treatment specifically focused toward lowering ICP should be implemented consistent with continued physiologic resuscitation.

The composition and volume of the IV fluids used to resuscitate patients with head injuries should be selected with the purpose of restoring intravascular blood volume. Although the widely disseminated but scientifically unsupported adage of “keeping TBI patients dry” has now been discarded, the concept of restricting free water remains desirable. As such, isotonic crystalloid solution in the form of 0.9% normal saline (NS) is preferable to lactated Ringer solution as a resuscitation fluid for TBI. For some time, a growing body of indirect scientific support appeared to support the use of 250 mL of 7.5% NS as the first resuscitation fluid in TBI victims.^{25–27} However, a recent randomized controlled trial from Australia has suggested that this may not be of benefit under optimal resuscitation conditions.²⁸ The branch of the ongoing Resuscitation Outcomes Consortium (ROC) Hypertonic Saline Trials focusing on prehospital treatment of TBI patients is currently attempting to readdress this problem.

The endpoints of resuscitation do not change depending on the presence or absence of a head injury. Blood volume should be normal, with an appropriate blood pressure and central venous pressure, adequate urine output and peripheral perfusion, and progressive improvement of any base deficit. The systolic blood pressure should never be allowed to drop below 90 mm Hg. Some evidence indicates an advantage to targeting a mean arterial pressure of 80 to 90 mm Hg during resuscitation until ICP monitoring can be initiated. Once ICP is available, a minimal CPP of 60 mm Hg should initially be the goal.

Resuscitation in the Absence of Clinical Signs of Herniation

Algorithm 19.2 is based on the Guidelines for the Management of Severe Brain Injury^{10,11,22} and the Guidelines for the Prehospital Management of Severe Brain Injury²⁰ for use by prehospital and initial at-hospital care providers and emergency physicians to guide decision making in resuscitating TBI victims and determining the necessity of ICP-lowering therapy. “Signs of increased ICP” implies pupillary abnormalities, motor posturing, or neurologic deterioration not related to medications. When these signs are not present, mannitol is not given and the goal of ventilation is eucapnia. When such signs are present, the patient is hyperventilated to a PaCO₂ of 30 to 35 mm Hg and mannitol may be given if the patient’s volume status is normal.

ALGORITHM 19.2. Prehospital evaluation and treatment of a patient with severe traumatic brain injury. “Signs of increased ICP” is the decision point for determining the necessity of intracranial pressure (ICP)-lowering therapy. These signs include pupillary abnormalities, motor posturing, or neurologic deterioration not related to medications. The order of steps is determined by the risk-benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to field management of such patients. (© R.M. Chesnut, MD., FCCM, reproduced with permission.)

Algorithm 19.3 is based on the Guidelines for the Management of Severe Brain Injury^{10,11,22} for evaluation and treatment of the severe TBI patient from arrival at the trauma center prior to the placement of an ICP monitor. As with any trauma patient, the first step is Advanced Trauma Life Support (ATLS) resuscitation. When appropriate, brain-specific therapies are incorporated into the treatment course. Brain-friendly initial ICU management should lead directly to monitoring of ICP.

Elevating the head of the bed (reverse Trendelenburg position in the absence of clearance of the axial skeleton) has been shown to generally lower the CPP in the absence of adequate volume resuscitation.²⁹ Because this may elevate the ICP per se, it is not advised until complete resuscitation has been accomplished.

The confusion and agitation often attendant to head injury often can drive intracranial hypertension and renders sedation desirable. Therefore, patients with suspected head injury should generally receive sedatives and analgesics whenever possible. Particularly in the TBI patient, the difference between sedation and analgesia should be kept in mind and the two agents titrated specific to their respective indications. Short-acting agents are preferable in the interest of following the neurologic examination.

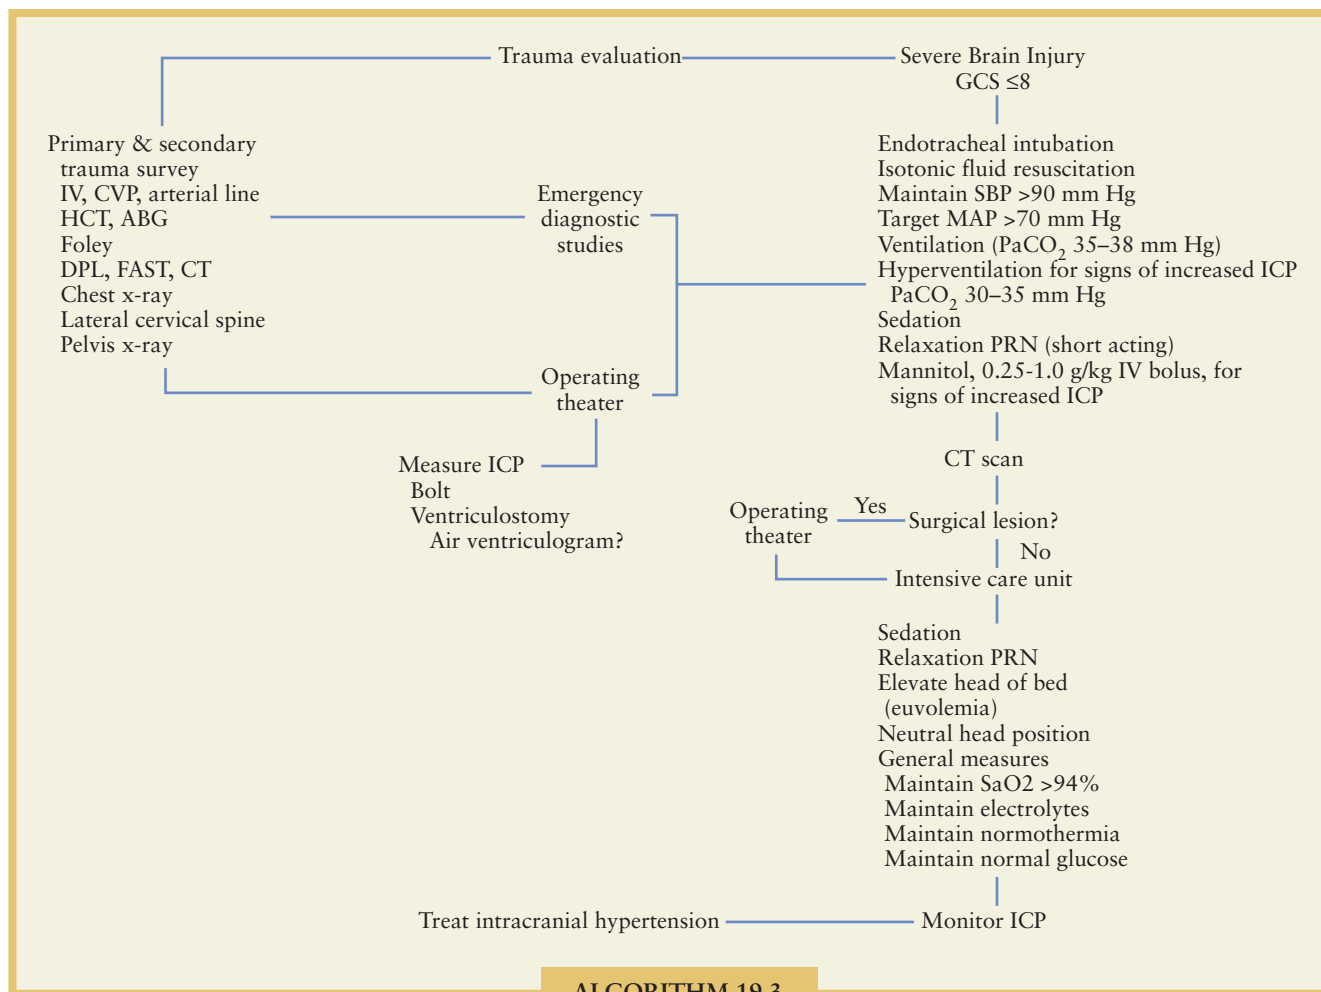

In addition to eliminating any possibility of spontaneous ventilation and mandating complete ventilatory control, pharmacologic relaxation has the undesirable effect of limiting the neurologic examination to the pupils and the CT scan. Its use in the absence of evidence of herniation, therefore, should be

limited to situations where sedation and analgesia alone are not sufficient to optimize safe and efficient patient transport and resuscitation.

The “prophylactic” administration of mannitol is not suggested, because of its volume-depleting diuretic effect. In addition, although it is desirable to approximate the lower end of the normal range of PaCO₂ during transport of a patient suspected of having brain injury, the risk of exacerbating early ischemia by vigorous hyperventilation outweighs the questionable benefit in the patient without evidence of herniation. Therefore, ventilation parameters consistent with optimal oxygenation and “normal” ventilation are recommended. The minute ventilation should be targeted at 100 mL/kg per minute until quantitative measurement of end-tidal carbon dioxide (EtCO₂) or PaCO₂ is available. The Guidelines for the Prehospital Management of Severe Brain Injury suggest the use of EtCO₂ monitoring during prehospital resuscitation and transport whenever possible. In the absence of signs of intracranial hypertension, ventilation should be adjusted to accomplish a PaCO₂ of 35 mm Hg when arterial gas values become available.

Resuscitation in the Presence of Clinical Signs of Herniation

Signs of intracranial hypertension consist of evidence of transtentorial herniation (pupillary dilation or loss of reactivity

ALGORITHM 19.3

ALGORITHM 19.3. Evaluation and treatment of the patient with severe traumatic brain injury on arrival at the trauma center. The order of steps is determined by the risk-benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to initial hospital management of such patients prior to the initiation of ICP monitoring. (© R.M. Chesnut, MD., reproduced with permission.)

or motor posturing or flaccidity) or progressive neurologic deterioration not attributable to other causes (e.g., sedation). When such signs occur, aggressive treatment of suspected intracranial hypertension is indicated. Hyperventilation to a PaCO_2 target of approximately 30 mm Hg should be accomplished by increasing the minute ventilation to approximately 120 to 140 mL/kg per minute or as directed by quantitative CO_2 monitoring. Because hypotension can produce both neurologic deterioration and intracranial hypertension, the use of mannitol is less desirable unless adequate volume resuscitation has been accomplished. If such is the case, however, mannitol should be administered by bolus infusion. Under such circumstances, it is critical that the diagnosis and treatment of the neurologic injury be accomplished with utmost haste. These patients must be transported to a trauma center with neurosurgical coverage.

Radiographic Priorities

5 Neurosurgical evaluation and assessment are initiated as soon as the potential for significant head injury is realized. Prompt radiographic evaluation is essential and CT scanning is the imaging modality of choice for virtually all acute neurologic conditions. Patients with mild head injuries can usually be

observed with sequential examinations and radiographic evaluation may be unnecessary unless the results determine whether the patient can be discharged from the hospital. In contrast, however, a cogent argument can be made for the liberal application of CT scanning to even patients with minimal evidence of TBI as a method of making safe, efficient, and economic triage decisions.³⁰ In any instance, evidence of neurologic deterioration or the occurrence of a situation wherein the neurologic examination cannot be followed (e.g., the need for general anesthesia) mandates CT scanning, intraoperative ICP monitoring, or both. General indications for neurologic imaging (generally, CT scanning) are listed in Table 19.1.

Patients with moderate or severe injuries require prompt neurosurgical consultation and rapid radiographic evaluation using the CT scanner. Hemodynamically stable patients with significant neurologic deterioration should go to the CT scanner immediately following ATLS resuscitation. In hemodynamically unstable patients who require immediate surgical intervention to sustain intravascular volume, lifesaving exploratory thoracotomy or laparotomy must take precedence. In such cases, it is a mistake to delay further investigation of the intracranial compartment pending the end of the case and transport to the CT scanner. A number of methods can be employed to evaluate the intracranial compartment during such lifesaving, extracranial surgery, including insertion of an

TABLE 19.1 **DIAGNOSIS****INDICATIONS FOR NEUROLOGIC IMAGING**

- Suspected skull penetration by a foreign body
- Discharge of cerebrospinal fluid (CSF), blood, or both from the nose
- Hemotympanum or discharge of blood or CSF from the ear
- Prolonged unconsciousness
- Altered state of consciousness at the time of examination
- Focal neurologic signs or symptoms
- Any situation precluding proper surveillance
- Head injury plus additional trauma
- Possible head injury in the presence of additional pathologic findings, such as stroke
- Head injury with alcohol or drug intoxication

ICP monitor or ventriculostomy (with air ventriculography, if deemed necessary), transcranial Doppler evaluation, or even placement of exploratory burr holes in the instance of herniation. For this reason, neurosurgical consultation should be initiated on arrival in theater rather than at the finish of the case.

At the other end of the spectrum, in cases where there is an obvious surgical brain injury, the choice and timing of diagnostic systemic maneuvers should be subject to modification. Such patients should be transported directly to theater and examinations such as focused assessment with sonography in trauma (FAST) or diagnostic peritoneal lavage performed as the patient is being prepped for craniotomy. In such instances, obviously, early communication between the trauma surgery and neurosurgery departments is critical.

The spine should be cleared radiographically or immobilized and protected in every patient with a severe head injury. Although only 13% of patients with severe head injuries have spinal cord injuries, the potentially devastating consequences of an overlooked spine injury require constant vigilance.

Plain Skull Radiographs. With the routine availability of 24-hour CT scanning capabilities, plain skull radiography has largely become obsolete in TBI. The likelihood of a surgical intracranial hematoma is strongly correlated with the presence or absence of a skull fracture if the neurologic examination is factored in.³¹ Nevertheless, the superiority of CT imaging in all aspects of evaluating TBI has relegated the use of skull films to unusual circumstances.

Computed Tomography. The CT finding that correlates most highly with intracranial hypertension is compression or obliteration of the basilar cisterns (Fig. 19.3). Not only does this finding portend a stormy ICP course, but also the primary predictor of outcome in patients with this CT picture is the peak level of intracranial hypertension occurring during the first 72 hours.^{32,33} When cisternal compression is paired with a midline shift of more than 5 mm, the prognosis is even more ominous. ICP monitoring should be immediately initiated in any patient with cisternal compression and intracranial hypertension should be vigorously treated. Such patients, particularly those with minimal evidence of contusions, die primarily from secondary brain insults, which implies that they are potentially salvageable.

Acute epidural hematomas correlate well with skull fractures. The most common association is a linear, nondisplaced fracture in the temporoparietal region, crossing the middle meningeal artery. The classic clinical course involves a lucid interval following a brief loss of consciousness with subsequent neurologic deterioration. However, such a course occurs in less than 50% of epidural hematoma cases, so clinical

FIGURE 19.3. A computed tomography scan that is highly predictive of intracranial hypertension. The basilar cisterns are obliterated and the sulci are flattened.

suspicion must remain high. The typical CT appearance is a high- or mixed-density concave extra-axial hematoma with smooth borders (Fig. 19.4).

Acute subdural hematomas occur over the convexity of the brain. The hematoma may evolve from rupture of bridging cortical veins or bleeding from the underlying parenchymal

FIGURE 19.4. Typical computed tomography scan appearance of mixed-density, lens-shaped, acute epidural hematoma with mass effect.

FIGURE 19.5. Usual computed tomography scan appearance of a crescent-shaped, high-density blood collection conforming to the contour of the cerebral hemisphere in a subdural hematoma.

FIGURE 19.6. Contusion and associated intracerebral hematoma in the frontotemporal area.

injury, the latter being a common source. It is this subjacent tissue damage that generally determines the neurologic outcome of patients not succumbing to intracranial hypertension. On CT scan, a subdural hematoma appears as an extra-axial high- or mixed-density crescentic mass that spreads out over the hemisphere, following the cortical irregularities (Fig. 19.5). The midline shift may be out of proportion to the size of the hematoma because of the contributing mass effect from an underlying brain contusion or hemispheric swelling.

Intracerebral hemorrhage and cerebral contusion are common after trauma and are readily visualized with CT scanning. Brain contusion appears as a focal, heterogeneous density with hemorrhage interspersed with injured tissue (Fig. 19.6). Intracerebral hematomas are generally more homogenous in their high-density appearance. Both of these lesions tend to “blossom” over time because of some continued hemorrhage and the development of edema. It is important, therefore, to closely observe and monitor the ICP of such patients because significant and hazardous mass effect may evolve, requiring surgical extirpation.

With temporal or deep frontal contusions, late deterioration may occur, generally because of progressive edema development. The peak of such deterioration appears to be around 1 week, although cases have occurred as late as 10 to 14 days. Most of these patients will complain of severe or increasing headache or their CT images will show progressive edema formation. As such, a high index of suspicion must be accompanied by liberal use of follow-up CT imaging and, in particular, not dropping the level of surveillance until both the clinical situation and the CT appearance are stable. In the instance of such lesions showing progressive mass effect, the insertion of an ICP monitor may be considered, even in a patient with a relatively high GCS score.

The typical CT appearance of subarachnoid hemorrhage is a layer of blood over the cerebral cortex, layering over the tentorium and commonly filling the basal cisterns. Cerebral

edema appears as areas of decreased density, which may be either focal or diffuse. Posttraumatic edema formation generally takes hours to days to develop unless compounded by hypoxia or hypotension. The “swollen brain” commonly seen in the setting of trauma may be caused by edema or increased CBV (unclotted, intravascular blood is low density). Diffuse axonal injury, typical of acute acceleration-deceleration injury, appears on CT scan as small areas of focal hemorrhage in the brainstem, thalamus or deep nuclear region, corpus callosum, and hemispheric white matter and may be accompanied by cerebral swelling. Finally, gunshot wounds or other penetrating injuries can be evaluated with CT scanning to allow accurate preoperative assessment of the anatomic injury for prognostic and therapeutic planning purposes.

One significant issue of recent origin is the “blossoming” or appearance of new lesions subsequent to CT images obtained at very short intervals following injury. Most of the “classic” TBI studies presented initial CT data from studies done hours following trauma. With improved prehospital transport and the ready availability of CT imaging, many initial studies are now performed 15 to 30 minutes after injury. As a result of such ultra-early CT scanning, there is now a risk of missing significant intracranial lesions by obtaining imaging before their appearance or during an early phase of their evolution. For this reason, in any patient with intracranial pathology or intracranial hypertension, we routinely obtain an early follow-up CT image at 4 to 6 hours after admission. Although such repeat imaging only uncommonly reveals new surgical pathology, documented lack of evolution may allow liberalization of the patient’s care plan (e.g., transfer out of ICU or allowance of nonemergent extracranial surgery). Alternatively, any evidence of progression on follow-up CT imaging mandates that no decrease in surveillance should occur until further imaging establishes stability. At the time of follow-up brain imaging, a CT scan of the cervical spine can also be done in an effort to facilitate its clearance.

Ancillary Imaging. As noted earlier, there is a significant association between TBI and injury to the axial skeleton, particularly to the cervical spine. In addition, particularly when associated with basilar skull fractures or facial fractures, TBI suggests the possibility of damage to the major arteries of the neck. As such, particular attention should be given to careful radiographic clearance of the spine and consideration of studies such as CT angiography of the great vessels rostral to the aortic arch.

DEFINITIVE MANAGEMENT

Surgical Decompression and Outcome

Skull Fracture (Including Basal Skull Fractures).

Depressed skull fractures are easily seen on plain frontal or lateral skull films and on CT. The mechanism of injury is usually a direct blow to the skull by a blunt object. Closed depressed skull fractures that are comminuted and those with a fragmented outer margin displaced beneath the inner table have characteristically been treated surgically, although growing evidence indicates that many may be treated nonoperatively if there is no neurologic dysfunction or CT evidence of underlying tissue injury. Open fractures are also generally treated surgically, although, again, growing evidence indicates that fresh, noncomminuted fractures without neurologic deficit, CSF or brain extrusion, gross contamination, or underlying tissue injury can be closed and treated with prophylactic antibiotics. When surgery is indicated, the goals are to débride the injury, accomplish secure CSF containment, restore cosmetic contours, and close the wound in a manner to ensure healing.

Basilar skull fractures are usually diagnosed with CT imaging or on clinical evidence, as they are poorly visualized on plain films. Clinical signs include otorrhea or rhinorrhea, subcutaneous ecchymoses overlying the mastoid region (Battle sign), bilateral periorbital ecchymoses (raccoon eyes), or hemotympanum. A basilar skull fracture may involve the paranasal sinuses, piriform sinus, petrous bone, sphenoid sinus, or sella turcica. Injuries to adjacent structures, such as the seventh or eighth cranial nerves, brainstem, and carotid or basilar arteries, are not uncommon. These are generally visualized with CT scanning, although special protocols may be required. If vascular injury is suggested (such as by fracture lines involving the carotid canal), CT or catheter angiography should be considered. In the acute CSF leak, no specific therapy is indicated. The leak should not be tamponaded unless it is brisk. Antibiotics should not be administered solely for prophylaxis of meningitis. Most CSF leaks stop spontaneously with minimal treatment (e.g., elevating the head of the bed). Leaks that continue more than 72 hours generally require temporary CSF diversion (e.g., via lumbar drainage or ventriculostomy). CSF drainage that does not respond to diversion will require surgery. Although most instances of rhinorrhea cease without surgery, the most common operation for persistent CSF leaks is exploration of the floor of the frontal fossa. The goal of such surgery is to identify the dural defect (often associated with herniation of a small tongue of brain tissue) and either close it primarily, patch it, or otherwise isolate the subarachnoid compartment from the skull base.

Mass Lesions. The possibility of a mass lesion must be entertained in any patient who develops evidence of herniation (see Fig. 19.2). Under optimal circumstances, this herniation can be reversed medically (with hyperventilation and hyperosmolar agents), allowing an emergent CT scan, which will demonstrate the location and size of any intracranial mass lesions and any herniation caused by nonsurgical processes.

When CT scanning is not immediately available or herniation is refractory to medical management, emergency trephining

FIGURE 19.7. Location for placement of initial exploratory burr hole in the temporal region for emergency diagnosis and decompression.

is a useful and lifesaving option. The first burr hole is placed in the ipsilateral temporal region and the dura is opened if an epidural hematoma is not in evidence (Fig. 19.7). If this exploration is negative, a second hole is placed in the opposite temporal region. If this is unrewarding, serial trephines are performed in the region of the parietal boss and the frontal convexity, first on the ipsilateral side, then contralaterally. A burr hole exploration is not negative until six holes have been drilled. A positive trephine is turned into a craniotomy, and the hematoma is thoroughly evacuated.

Epidural Hematomas. Epidural hematomas are frequently of arterial origin and have a tendency to expand. Prognosis varies directly with level of consciousness at time of surgery, ranging from 0% mortality for patients conscious throughout, to 27% with the classic lucid interval, to over 50% if the patient never regains consciousness. Aggressive surgical management has resulted in an overall mortality of about 9%.³³

The recommendations regarding the management of epidural hematomas contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: an epidural hematoma larger than 30 mL, clot thickness greater than 15 mm, or midline shift over 5 mm should be surgically evacuated regardless of the patient's GCS score. In patients with a GCS score of 8 or less, evacuation should be emergent. If the GCS score is higher than 8, evacuation should be done as soon as possible but must not interfere with other resuscitative efforts unless there is evidence of progressive deterioration. It is strongly recommended that patients with any acute epidural hematoma with anisocoria undergo surgical evacuation as soon as possible. Epidural hematomas of less than 30 mL, clot thickness below 15 mm, and midline shift less than 5 mm should be considered for evacuation because the risk of evacuation appears less than the dangers of enlargement and neurologic injury. Epidural hematomas of this size in patients with GCS scores above 8 may be considered for nonoperative management, including frequent neurologic monitoring in an ICU setting and serial CT imaging. Although the mean time for enlargement of such lesions is approximately 8 hours after trauma, they may occur at intervals up to 36 hours.

Subdural Hematomas. Subdural hematomas are the more common extra-axial mass lesion, particularly in non-motor-vehicle trauma. For subdural hematomas, the prognosis is less

optimistic, with mortality rates of approximately 50%. To a great extent, this is related to the often significant injury to the underlying brain.

The recommendations regarding the management of subdural hematomas contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: an acute subdural hematoma with a thickness greater than 10 mm or midline shift above 5 mm on CT should be surgically evacuated, regardless of the patient's GCS score. Evacuation should be on an emergency basis if the initial GCS score is less than 8. In patients with higher GCS scores, evacuation should be as soon as reasonably possible. A comatose patient (GCS score ≤ 8) with a subdural hematoma with less than 10 mm thickness and midline shift below 5 mm should undergo surgical evacuation of the lesion if any of the following apply:

- The GCS score decreased between the time of injury and hospital admission by 2 or more GCS points.
- The patient presents with asymmetric or fixed and dilated pupil(s).
- The ICP exceeds 20 mm Hg.

Patients with subdural hematomas of less than 10 mm thickness and midline shift below 5 mm and GCS scores greater than 8 can be treated nonoperatively.

It appears that outcome from subdural hematomas is proportional to the timing of evacuation. When surgery is planned, it should be performed within 4 hours whenever possible.³⁴ If surgical evacuation of an acute subdural hematoma in a comatose patient (GCS score ≤ 8) is indicated, it should be done using a full craniotomy with or without bone flap removal and duraplasty.

All patients with acute subdural hematoma and coma (GCS score < 9) should undergo ICP monitoring, including in the initial stages following evacuation.

Frequently, consideration is given to leaving off the bone flap and performing a duraplasty following the evacuation of acute subdural hematomas, particularly when the surgeon feels that there is evidence of brain swelling. Unfortunately, there is a relative dearth of information on this group of patients. An "in press" study of 155 such patients at Harborview Medical Center reveals that it appears to be effective in patients younger than 50 years of age and should be considered when the preoperative CT reveals intraparenchymal lesions or significant subarachnoid hemorrhage (Marcelo Vilela, unpublished data). In that group, the most powerful predictors of outcome in terms of variables amenable to clinical manipulation were postoperative intracranial hypertension (> 35 mm Hg), CPP less than 60 mm Hg, or intraoperative hypotension (< 90 mm Hg).

Parenchymal Lesions. Surgery for intraparenchymal mass lesions remains controversial. Arguments against surgery include the risks of the operation itself as well as damage to tissue that may otherwise go on to recover. Arguments for surgery focus on preventing the hazards of intracranial hypertension caused by the lesion itself or progressive edema formation as the lesion matures. Much of the difficulty in determining the applicability of surgery in individual situations arises from our inability to consistently predict which patients will rapidly deteriorate (e.g., proceed on to herniation) or fail nonoperative therapy by developing intracranial hypertension refractory to medical therapy. Unfortunately, this controversy has not been adequately addressed by well-done clinical investigations, so recommendations remain based on class III evidence. One thing that does appear consistent is that lesions of the anterior temporal lobe or the deep basilar frontal lobe are particularly dangerous because of the risk of precipitous herniation without impressive ICP elevation.

The recommendations regarding the management of traumatic parenchymal lesions contained in the Guidelines for the

Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: in general, patients with any lesion greater than 50 mL in volume should be treated operatively. Additionally, patients who have parenchymal mass lesions and signs of progressive neurologic deterioration referable to the lesion, medically refractory intracranial hypertension, or signs of mass effect on CT scan should be considered for surgery.

Patients with GCS scores of 6 to 8 should be treated operatively if they have frontal or temporal contusions greater than 20 mL in volume with either midline shift over 5 mm or cisternal compression on CT scan.

Patients with parenchymal mass lesions may be managed nonoperatively if they do not show evidence for neurologic compromise, have controlled ICP, and have no significant signs of mass effect on CT scan. Such patients should be managed with intensive monitoring and serial imaging. Surgery should be readdressed if difficulties with control of intracranial hypertension lead to consideration of "second tier" therapies (e.g., hypothermia or barbiturate coma) so as to avoid the secondary complications of such therapy. In all nonoperatively treated patients with parenchymal mass lesions, surgery should be considered before reaching the medical "point of failure."

Surgical management may involve decompression to "make room" for the lesion-induced swelling, evacuation and débridement of the offending lesions, or a combination. Because evacuation of such lesions does not always eliminate the development of intracranial hypertension, extensive craniotomy with expansible duraplasty and without replacing the bone flap should be considered at the time of operation.

Diffuse Injury. The mortality rate of diffuse brain injury is directly related to the significance of the associated intracranial hypertension. As such, the mortality rate of diffuse injury with open basilar cisterns is approximately 13%, whereas compression or absence of cisterns has an associated mortality rate of about 38%. Diffuse injuries are not amenable to surgical therapy unless decompressive craniectomy is indicated for control of intractable intracranial hypertension.

Diffuse axonal injury is a reasonably distinct subset of diffuse brain injury. It is characterized on CT scan as small areas of focal hemorrhage in the brainstem, thalamus or deep nuclear region, corpus callosum, and hemispheric white matter, which may be associated with cerebral swelling. Intracranial hypertension is an inconsistent part of this syndrome. When ICP is elevated, however, successful management improves outcome. These patients tend to recover to varying extents; many of them will significantly improve in their level of consciousness but will generally be left with diffuse neurologic deficits (e.g., spasticity, cognitive impairments). Although a favorable prognosis seems to be correlated with fewer lesions on imaging studies and early improvement in level of consciousness, prognostication is difficult in individual cases of diffuse axonal injury.

Posterior Fossa Lesions. Posterior fossa lesions are particularly dangerous because the progression from a benign lesion to a critical lesion is so precipitous and deadly. Patients may rapidly deteriorate from awake and alert to comatose, with signs of herniation ("upward" [caused by uncompensated swelling in the posterior fossa] or "downward" [from hydrocephalus]). Because of difficulties with the technology and uncertainty as to what pressures might be critical, monitoring of posterior fossa intracranial pressure is rarely performed. Vigilant clinical observation, tempered with a high degree of preemptive concern, therefore, represents the only form of monitoring currently applicable.

The recommendations regarding the management of traumatic posterior fossa lesions contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: rapid suboccipital craniectomy for

evacuation of acute traumatic posterior fossa mass lesions is recommended in patients with neurologic dysfunction or deterioration referable to the lesion or mass effect on CT scan. Mass effect on CT scan appears as distortion, dislocation, or obliteration of the fourth ventricle; compression or loss of visualization of the basal cisterns; or presence of obstructive hydrocephalus.

In general, surgery is recommended for any clot larger than 3 cm in diameter, whereas conservative management may be considered with clots smaller than 3 cm when not associated with acute subdural or epidural hematomas. Because of the potential for rapid, unheralded deterioration, evacuation should be performed as soon as possible in patients with indications for surgical intervention.

Depressed Skull Fractures. Skull fractures are a common result of head trauma and, when closed and not displaced, rarely require treatment per se. When displaced (generally defined as beyond the inner table of the skull), surgical intervention should be considered for the management of underlying intracranial pathology or cosmesis. The best available evidence does not support elevation for the prevention or treatment of epilepsy. As such, nonoperative management of closed (simple) depressed skull fractures is a routine treatment option.

The recommendations regarding the management of traumatic open (compound) depressed skull fractures contained in the Guidelines for the Surgical Management of Traumatic Brain Injury²⁴ can be summarized as follows: treatment of open, depressed fractures is focused primarily on avoidance of infection. Cosmesis is a secondary consideration. In general, patients with open (compound) skull fractures depressed greater than the level of the skull inner table should undergo operative intervention to prevent infection. Indications for nonoperative management are given in Table 19.2.

When surgery is indicated, early operation is recommended to reduce the incidence of infection. Elevation and débridement is recommended as the surgical method of choice. Primary bone fragment replacement is a surgical option in the absence of wound infection at the time of surgery.

All management strategies for open (compound), depressed fractures should include antibiotics regardless of whether surgery is undertaken. The exact nature of the antibiotics used and the duration of treatment remain inadequately delineated in the existing literature. The general tendency is the use of broad-spectrum antibiotics (vs. gram-positive and gram-negative aerobic and anaerobic bacteria) for 1 to 2 weeks.

Penetrating Injuries. Penetrating injuries to the brain present several unique management problems, including the prophylaxis and treatment of intracranial infection, the possibility of epilepsy, and the risk of occult vascular injuries. The recommendations regarding the management of penetrating

brain trauma contained in the Guidelines for the Management of Penetrating Brain Injury²³ can be summarized as follows: Although plain radiographs may be useful in determining intracranial trajectory, CT scanning of the head is the modality of choice in penetrating brain injury (PBI). In addition to the standard axial views with bone and soft tissue windows, coronal sections may be helpful in patients with skull base or high convexity involvement.

Angiography or CT angiography should be considered in patients with PBI. It is strongly recommended in cases in which the wound's trajectory passes through or near the Sylvian fissure, supraclinoid carotid, cavernous sinus, or a major venous sinus because of the increased risk of traumatic aneurysm or arteriovenous malformation. Sentinel signs of vascular abnormalities are large initial hematomas or the delayed development of substantial and otherwise unexplained subarachnoid hemorrhage or hematoma. When discovered, such vascular lesions should be definitively managed.

A major complication of penetrating injury is infection, both meningitis and abscess. Most infections occur within 3 weeks (55%) to 6 weeks (90%). The major risk factors appear to be CSF leaks, air sinus wounds, or wound dehiscence. The incidence of infection with the use of broad-spectrum antibiotic treatment ranges from 1% to 11%. Although the main causative agent appears to be *Staphylococcus*, gram-negative bacteria are also frequent and *Clostridium* or other anaerobic organisms may be found with appropriate culture techniques. As such, antibiotic prophylaxis is indicated in all penetrating injuries. The choice of antibiotics and the proper duration for their administration have not been formally investigated. Broad-spectrum regimens, including anaerobic coverage, lasting for 7 to 14 days appear to be a reasonable approach.

Seizures are much more frequent following PBI than non-penetrating injury in general. Between 30% and 50% of patients with PBI develop seizures; 4% to 10% of those have their first seizure within the first week after injury and 80% during the first 2 years. About 18% may not have their first seizure until 5 or more years after injury. The risk decreases markedly with time. When followed for 15 years after a PBI, nearly 50% of patients with epilepsy eventually stop having seizures. Of patients with PBI, 95% remain seizure-free if they have no seizures during the first 3 years after injury.

Although there is a distinct lack of rigorous study, the increased incidence of early seizures has led to the recommendation that antiseizure medications (e.g., phenytoin, carbamazepine, valproate, phenobarbital) should be used during the first week after PBI. Prophylactic treatment with anticonvulsants beyond the first week after PBI has not been shown to prevent the development of new seizures and is not recommended.

The surgical management of penetrating wounds to the brain has undergone significant evolution over the past two decades. In the more distant past (and until recently, in terms of U.S. military policy), it was routine to fully explore penetrating injury tracts to completely remove all foreign substances. Reoperation was common for this purpose. Based on class III evidence from military actions of other countries (most from the Middle East), however, it is now recognized that outcomes are not measurably worse in patients who do not undergo aggressive débridement. At present, surgical débridement of the missile tract in the brain is not recommended in the absence of significant mass effect. As well, routine surgical removal of fragments lodged distant from the entry site or reoperation solely to remove retained bone or missile fragments is not recommended.

Treatment of small bullet entrance wounds to the head in patients whose scalp is not devitalized and have no significant intracranial pathology should consist of local wound care and closure. In more extensive wounds with nonviable scalp, bone, or dura, surgical management with more extensive débridement

TABLE 19.2 INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR NONOPERATIVE MANAGEMENT OF COMPOUND DEPRESSED SKULL FRACTURES

No clinical or radiographic evidence of:

- Gross wound contamination
- Significant intracranial hematoma
- Gross cosmetic deformity
- Frontal sinus involvement
- Dural penetration
- Depression >1 cm
- Wound infection
- Pneumocephalus

followed by primary closure or grafting to secure a watertight wound is recommended. Closure of the dura and prevention of CSF leakage are extremely important goals in managing penetrating wounds. In patients with significant fragmentation of the skull, débridement of the cranial wound with either craniectomy or craniotomy is recommended.

Mass lesions should be surgically managed to prevent intracranial hypertension. As such, débridement of necrotic brain tissue and safely accessible bone fragments is recommended when they produce significant mass effect. As well, evacuation of intracranial hematomas is recommended if they produce significant mass effect as defined by the production of midline shift of over 5 mm or intracranial hypertension. This is one of the reasons that monitoring of ICP in penetrating injuries is an important adjunct to surgical decision making.

Repair of an open-air sinus injury with watertight closure of the dura is recommended.

Decompressive Craniectomy for Control of Intracranial Hypertension

Craniectomies done in conjunction with hematoma evacuation (usually on admission) must be separated from craniectomies done only for brain edema treatment (ICP/CPP management). The former consist of “leaving the bone out” and not closing the dura after surgery, which is done to evacuate extra-axial or intracranial mass lesions. Such surgery, per se, is not done simply to increase the size and compliance of the cranial compartment to allow for brain swelling. This procedure was discussed earlier in the section on subdural hematomas.

Craniectomies done solely to treat brain swelling involve intentionally removing very large bone flaps, leaving them out, and performing duraplasties to prevent the dura from constraining the bulging brain. The most common scenario is that of diffuse swelling wherein bilateral frontotemporoparietal flaps are removed. When edema is localized primarily to one hemisphere (producing intracranial hypertension with midline shift), unilateral craniectomy is usually performed. In both cases, the bone flaps are as large as possible and particular attention is paid to removing the temporal squame forming the lateral wall of the middle cranial fossa.

Other surgical approaches to managing the swollen brain include subtemporal decompression and temporal lobectomy. In subtemporal decompression, the procedure is focused entirely on removing the lateral wall of the middle cranial fossa to decompress the temporal lobe. Temporal lobectomy involves removing a portion of the temporal lobe to “make room.” The right temporal lobe is generally chosen because of its less elegant nature. By definition, the operation involves removing undamaged or only partially damaged brain, which certainly decreases its attractiveness when alternatives exist. In addition, it is generally realized that the amount of room made by such operation is rapidly filled by swollen brain such that intracranial hypertension often soon returns. In the author’s practice, this operation has been completely replaced by decompressive craniectomy.

The goal of decompressive craniectomy is to completely obviate further ICP treatment, whenever possible. To this end, extensive bone removal and duraplasty are recommended.

Although it has not been rigorously studied in well-controlled prospective fashion, the present evidence base definitely supports decompressive craniotomy within 48 hours of injury as a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension. One of the difficulties in determining the proper timing for such a procedure is the issue of when intracranial hypertension becomes medically refractory. The

point of failure of second-tier treatments is a clear but quite delayed threshold point. In general, decompressive craniectomy should be considered as an option to instituting such second-tier treatment. In the interest of performing decompression before damage occurs from ICP elevation or cerebral ischemia, many support its use prophylactically as soon as a high degree of suspicion arises that medical management will fail before ICP control is attained. Examples of such decision points are patients with diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation (e.g., obscuration of the basal cisterns or midline shift >5 mm) where the initial ICP is very high or where early management requires rapid escalation in the intensity of treatment.

Intracranial Pressure Monitoring. All patients with severe brain injuries and a significant percentage of those with moderate injuries require continuous ICP monitoring. The most recent revision of the Guidelines for the Management of Severe Brain Injury indicates that class II evidence supports monitoring of all patients with a postresuscitation GCS score equal to or less than 8 who have any CT evidence of intracranial pathology.¹¹ Class III level evidence supports monitoring in patients with severe TBI and a normal CT scan if they have two or three of the following: (a) age older than 40 years, (b) any history of hypotension, or (c) abnormal motor posturing. ICP monitoring in other patients is left to the discretion of the physician. ICP monitoring should be considered in any patient with a GCS score of 12 or less who cannot be closely monitored clinically or whose CT scan demonstrates evidence of intracranial hypertension (i.e., mass lesion, obscured or absent basal cisterns, or midline shift).

Although many techniques are available, the most common involve small fiberoptic or strain gauge catheter tip pressure sensors placed several millimeters into the brain or fluid-coupled catheters placed into the lateral ventricles. The minimally invasive catheters are reliable and have a very low complication rate, making them an ideal choice in instances where a minimum-risk ICP monitoring technique is desired (e.g., in a moderate head injury that needs general anesthetic). They are also useful when the ventricles are too small to cannulate or there is an uncorrected coagulopathy. Ventriculostomy catheters have the added capability of allowing CSF drainage for ICP control. They are technically more difficult to place, however, and the complication rate is somewhat higher. In any case, safe and effective monitoring technology is available for any instance in which ICP monitoring is desired.

Monitoring ICP not only provides early warning of herniation but also, by allowing calculation of CPP, opens up the possibility of more precisely optimizing CBF and preventing ischemic secondary brain injury. Because all methods of lowering ICP or raising CPP have potentially harmful side effects, using such agents to treat suspected intracranial hypertension without monitoring ICP is not recommended.

Monitoring of Cerebral Ischemia. One of the major influences of ICP on outcome is its interference with cerebral perfusion. It is concern for this aspect that has prompted the widespread incorporation of CPP management into TBI treatment as a rough estimate of cerebral vascular resistance. Much research has been done on cerebral perfusion after TBI but, given the variability of the cerebral metabolic rate following TBI, due to both injury- and treatment-related factors, it is much more valuable to monitor for cerebral ischemia. As noted previously, there are currently several methods that are readily clinically available for ICU measurement of the adequacy of cerebral oxygen delivery. Placing a catheter into the jugular bulb via a retrograde venous route allows sampling of the saturation of oxygen in the blood leaving the brain. Jugular

venous oxygen saturation values below 50% are associated with cerebral ischemia and worsened recovery, whereas saturations above approximately 85% suggest hyperemic flow. Unfortunately, this method averages a large volume of the brain and does not include blood from all of the supratentorial parenchyma so that it cannot completely rule out ischemia. Looking for increased cerebral lactate production has been offered as a method of detecting cerebral ischemia that might be masked by the mixing of blood from ischemic and nonischemic areas, but the sensitivity of this measurement appears limited.

An alternative monitoring method is the insertion of an oxygen-sensing (Clark) electrode into the brain parenchyma to measure P_{bO_2} . P_{bO_2} values of less than 20 mm Hg are suggestive of ischemia. There is a growing body of evidence supporting the utility of this method, although definitive studies remain to be done. This technique samples only a very small, focal volume of tissue, so its placement is a matter of some discussion. At present, it is generally placed into normal brain, although some argue that trying to place it into the penumbra of an injury site would be preferable.

Cerebral microdialysis constitutes a third method of monitoring for evidence of cerebral ischemia by allowing the measurement of tissue lactate and pyruvate and calculating the lactate/pyruvate ratio. Like P_{bO_2} monitoring, this newer technique also samples a very focal region. At present, although cerebral microdialysis is very sensitive and is being used with growing frequency, it is primarily considered as a research tool.

Of note, these monitors are not mutually exclusive. They may be used to supplement each other or to verify findings from one technique that are suspect. Such a consideration becomes particularly important when significant prolongation or escalation of therapy is being considered based on an abnormal value from one monitoring system.

MEDICAL MANAGEMENT

General Measures

Aggressive restoration of intravascular volume, maintenance of adequate cerebral perfusion pressure, and avoidance of hypoxia are *conditiones sine quibus non* of medical treatment for intracranial hypertension. Volume resuscitation should be vigorous and thorough, with a target of euvolemia. The poorly founded, dangerous, and outmoded practice of restricting fluid volume should be abandoned. Restrict free water by using isotonic fluids, which makes normal saline preferable to lactated Ringer solution. Optimally, continuous monitoring of central venous and arterial pressures should be instituted early.

Control of pain and the response to noxious stimulation is necessary to avoid iatrogenic elevation of ICP. It should not be assumed that the comatose patient has a blunted pain response. Analgesia should be combined with sedation, using short-acting agents whenever possible to facilitate repeated neurologic examination. It is preferable to use sedatives that concomitantly decrease cerebral metabolism to increase the margin for hypoperfusion tolerance. Propofol and dexmedetomidine hydrochloride are good choices in adults for this reason.

The Guidelines for the Management of Severe Brain Injury do not support the early administration of antiepileptic medication for the prophylaxis of late seizures.¹¹ With respect to the prevention of early seizures (e.g., occurring within 10 to 14 days), prophylaxis does decrease their frequency but without proved benefit to outcome. As such, administration of antiepileptic agents for the first 2 weeks is at the discretion of

the physician. One reasonable approach is to treat only in cases where seizures could compromise tenuous ICP control or when seizures are likely not to be detected (e.g., during neuromuscular blockade).

Fever will elevate ICP and is independently correlated with decreased recovery in severe TBI.³ Local measures (e.g., cooling blankets, fans) should be used in conjunction with acetaminophen to keep temperatures below 37.5°C to 38°C when ICP requires treatment. Scheduled indomethacin may prove effective in cases where acetaminophen is not.

Venous drainage of the brain should be facilitated by avoiding constriction of the jugular system in the neck and elevating the head of the bed in euvoletic patients. In addition, attention should be paid to intrathoracic pressures, particularly when considering the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Increased intra-abdominal pressure can also embarrass jugular drainage and elevate ICP.

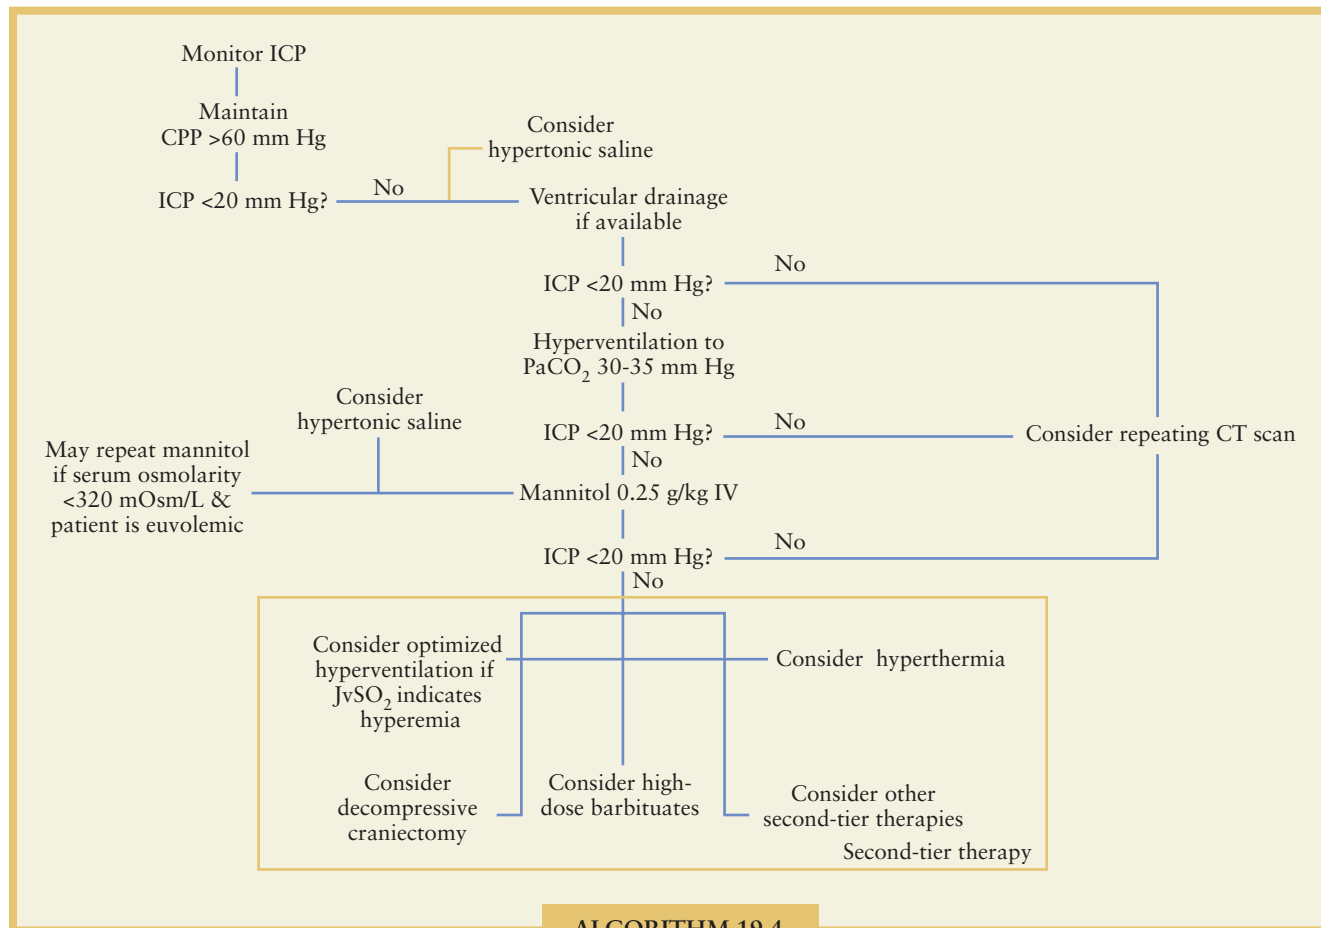

Finally, meticulous general critical care is important, because the protracted ICU stay and the necessity for intubation, mechanical ventilation, and other artificial support systems significantly increase the risk of nosocomial and iatrogenic complications.

Recent investigations in the trauma population in general have demonstrated an increased risk of complications, such as the acute respiratory distress syndrome and the systemic inflammatory response syndrome, in patients who undergo transfusion. This has led to a reticence to transfuse and a strong tendency toward accepting hematocrit levels in the low 20s. On the other hand, evidence indicates that the injured brain is exquisitely sensitive to secondary insults such as ischemia. Unfortunately, there is little evidence that the damage caused by such events can be treated or reversed so that the general neurosurgical recommendation is to maintain an oxygen-carrying capacity that is higher than that afforded by such low hemoglobin levels, more commonly striving to values of approximately 30. As such, when the question of cerebral oxygenation arises in the setting of a hematocrit between approximately 21 and 30, monitoring the adequacy of cerebral oxygen delivery (e.g., by following jugular venous saturation or brain tissue oxygen tension) should be considered. In the absence of definitive studies, the choice of a general, empirical threshold for transfusion remains nebulous.

Control of Established Intracranial Hypertension. All of the previously discussed “pre-ICP monitoring” steps may be used in direct response to intracranial hypertension, their application and intensity tapered to achieve ICP control. These interventions should be considered the basic steps in this respect and should be optimized prior to adding further treatments.

6 Cerebrospinal fluid drainage, hyperventilation, mannitol, barbiturates, and so on are the mainstays of therapy to control documented intracranial hypertension. Each, however, has significant potential complications, which can obviate their beneficial effects. Therefore, they should not be employed unless intracranial hypertension is established by monitoring, and caution and vigilance must attend their usage. Although the treatment of intracranial hypertension is not the primary focus of this chapter, some brief comments will be useful.

As noted, the treatment of intracranial hypertension should be initiated on a base of adequate sedation and analgesia, control of fever, and optimization of systemic physiologic conditions that might exacerbate ICP elevation (e.g., intrathoracic pressure). Neuromuscular blockade may be added to sedation and analgesia if further ICP control is desired. It does not always work, so a trial is often considered. Blockade to the level of one to two twitches out of a train-of-four is a reasonable target in this population.

ALGORITHM 19.4

ALGORITHM 19.4. Treatment of established intracranial hypertension, based on the Guidelines for the Management of Severe Brain Injury. The order of steps is determined by the risk-benefit ratio for individual treatment maneuvers. This algorithm should be viewed as “expert opinion” and used as a framework, which may be useful in guiding an approach to elevated ICP.

Treatment for intracranial hypertension in adults from the original edition of the Guidelines for the Management of Severe Brain Injury is outlined in Algorithm 19.4. When consulting this algorithm, remember that it represents a consensus opinion (class III evidence) and that, for this reason, a treatment algorithm was not included in the 2008 revision (being left to subsequent, currently ongoing construction by a consensus development team). When this algorithm was developed, the role of hypertonic saline was not addressed.

When available via ventriculostomy, CSF drainage should be the first method of managing intracranial hypertension. There is no consensus on what pattern of drainage is most efficacious. It must be noted that ICP measurement cannot be performed when the ventricular catheter is open to drain. For this reason, we generally drain against approximately 10 cm H₂O for 2-minute intervals, then reclamp the catheter and measure the ICP. Requiring such cycling more than five times in 1 hour constitutes a need for consideration of therapeutic escalation.

As discussed, mannitol is useful for treating intracranial hypertension. There are no specific physiologic indications for the use of mannitol over other agents. Mannitol should be avoided under conditions of hypovolemia or increased serum osmolality (i.e., >320 mOsm/L). When administered, mannitol should be given as a bolus. It appears that lower doses (e.g., 0.25 g/kg) may be equally as effective in lowering ICP as larger doses (e.g., 1 g/kg).¹¹ No adequate evidence exists to guide the

choice between mannitol and hypertonic saline when osmolar treatment is being considered.

Hypertonic saline is becoming an increasingly common tool in the management of traumatic brain injury. Its efficacy in reversing intracranial hypertension has been best demonstrated in children, where administration of 3% NaCl to osmolality thresholds of up to 360 mOsm/L and serum sodium levels of up to 160 mEq/L are tolerated. Because of a lack of outcome-based studies, however, the independent ability of such treatment to improve outcome remains unclear.

There has been a strong tendency to extrapolate such use of hypertonic saline to the treatment of intracranial hypertension in adults where it has been less well studied. For continuous intravenous infusion, doses are generally in the 0.5- to 1.0-mEq/kg per hour range and concentrations of 3% to 5% are commonly used. For “bolus” injection in response to an episode of intracranial hypertension, concentrations ranging from 3% to 23% are being used with the caveat (noted earlier) that the rate of injection of the higher concentrations into central lines should be limited in view of transient adverse effects on myocardial conductivity.

The tolerable limits for serum osmolality and sodium levels have not been well defined in adults, but the levels used in children appear to be reasonably tolerated. A risk of rebound cerebral edema appears to exist when levels are allowed to drop too quickly after the administration of 3% saline is stopped. Our present practice is to not consider the patient “out of the

woods” for such rebound until the serum sodium has returned to within normal limits. As such, we generally leave the ICP monitor in place and caution against major, nonemergent surgical cases.

Hyperventilation is generally effective in lowering ICP. As noted, however, it works on the arterial side, via vasoconstriction-induced decreases in CBV, which allows the possibility of inducing ischemia by embarrassing CBF. At present, no clinically applicable method exists for measuring CBV, and it is unclear how often elevated CBV per se is a primary physiologic abnormality in intracranial hypertension. Therefore, lowering CBV to treat intracranial hypertension includes risks that need be minimized.

In keeping with the Guidelines for the Management of Severe Brain Injury, hyperventilation ($\text{PaCO}_2 < 35$ mm Hg) should be avoided during the first 24 hours following TBI.¹¹ Thereafter, if intracranial hypertension continues, hyperventilation to PaCO_2 values between 30 and 35 mm Hg may be considered. Whenever hyperventilation is used, and certainly when PaCO_2 values of less than 30 mm Hg are targeted, methods of monitoring the effects on CBF or flow-perfusion matching should be considered, such as quantitative CBF measurement, jugular venous saturation monitoring, or following cerebral tissue oxygen saturation.

7 When ICP control does not respond to these management steps, second-tier therapies should be considered. These include barbiturate therapy, hypothermia, decompressive craniectomy, and optimized hyperventilation (among other approaches). The details of the choice between second-tier agents are beyond the scope of this chapter. In general, the choice should be based on and directed using as much multimodality monitoring as is available, because the risk-benefit ratio of most of these treatments is very narrow.

CHAPTER 20 ■ MAXILLOFACIAL TRAUMA

RICHARD A. HOPPER AND JOSEPH S. GRUSS

KEY POINTS

- 1 Maxillofacial trauma is directly related to social structure, geography, and economics. Facial injury patterns vary according to age, risk taking, and daily activities.
- 2 Facial trauma is common (up to one third of all multisystem trauma patients), is frequently associated with life-threatening injuries, and should provide a warning of potential concomitant airway, central nervous system, and orthopedic injuries.
- 3 Initial management of maxillofacial trauma follows Advanced Trauma Life Support (ATLS) principles and involves airway management, control of hemorrhage, and rapid identification of injuries with significant morbidity, ocular injury, cerebrospinal fluid leakage, neurologic damage, and malocclusion.
- 4 Structured history and physical examination and computed tomography scan-guided diagnosis with reconstruction of major facial buttress damage using open reduction and internal fixation in a timely fashion are critical to optimize final functional and esthetic outcome.

Facial trauma often accompanies life-threatening injuries and is a warning of concomitant airway, central nervous system, visceral, and orthopedic injuries.¹ Although it is the associated life-threatening injuries that demand immediate attention, it is the severity of facial trauma that has a direct correlation with the ability of patients to return to preinjury work.² Because of the significant role that facial appearance serves in our ability to function daily, and the density of functional units within the craniofacial skeleton, injuries in this region can cause lifelong debility that precludes functioning in society.

The current management of complex facial trauma aims to restore and maintain the normal anatomy of the craniofacial skeleton. Comprehensive clinical examination and computed tomography are used to establish the severity and extent of facial fractures and to identify injuries that require urgent treatment. Definitive operative treatment is performed as soon as the patient is stable in order to minimize the secondary problems of massive edema, bony collapse, and soft tissue shrinkage. Craniofacial surgical techniques are employed to expose the facial skeleton through limited incisions, to achieve anatomic reduction of the fractures, to restore occlusion and orbital volume, and then to use rigid internal fixation for stabilization of the reconstructed skeletal framework for uncomplicated fracture healing. Since the long-term results of timely treatment far exceed those of delayed treatment, it is essential that the definitive care phase of a trauma victim include the early detection, evaluation, acute management, and appropriate referral of maxillofacial injuries.

EPIDEMIOLOGY

Maxillofacial trauma includes soft tissue injuries, dentoalveolar damage, facial bone fractures, and combinations of these.

- 1 The epidemiology of these injuries is directly related to social structure, geography, and economics, all of which influence the activities of a population. There is consequently significant regional and national variability in the etiology and incidence of maxillofacial trauma patterns.¹⁻³ Despite this epidemiologic variation, maxillofacial injuries are relatively common in all societies, and are present in up to one third of seriously injured patients with multisystem trauma.⁴

The incidence of facial trauma as a whole peaks in the first decade of life and slowly degrades over the remaining decades of life.^{1-3,5} The incidence of facial bone fractures, on the other hand, peaks in the third decade of life. Counter to the trend of increasing incidence of facial bone fractures in the first three decades of life, the actual relative risk per accident of facial bone fractures increases with increasing age (4.4% per year of life) due to the associated decrease in bone density.¹ Most injuries in the first decade of life are isolated soft tissue lacerations and/or dentoalveolar trauma (tooth impaction, alveolar process fractures, crown fractures, etc.) as opposed to the facial bone fractures seen in the adult population.

The etiology of facial trauma includes motor vehicle collisions (automobile, motorcycle, bicycle, and pedestrian), interpersonal violence, falls, industrial mishaps, sports-related injuries, and ballistic injuries. In the United States and Japan, motor vehicle collisions and interpersonal violence continue to be the major causes of facial bone fractures,^{2,5} whereas in European studies, sports and activities of daily life incidents are predominant.¹ There is also a relationship between mechanism of injury and age. Over all age groups, motor vehicle collisions are the predominant mechanism of injury for inpatient facial fractures. In infants and toddlers (age 0 to 4 years), falls are the second most common mechanism; in the early school years (age 5 to 14 years), pedestrian and bicycle collisions are the second most common mechanism. After age 14, violence and assault become more common.⁶

- 2 Approximately 20% of all facial soft tissue, dentoalveolar, and facial fracture trauma patients have associated injury to additional organ systems.¹ Motor vehicle collision victims with facial injuries have a relatively high associated rate of neurologic (32%), orthopedic (31%), visceral (24%), and ophthalmologic (14%) injuries. Personal assault has a lower association with neurologic (11%) and ophthalmologic (4%) injuries.³ When facial fractures are present in patients suffering an occupational injury, there is an average of four associated injuries for every facial fracture present, and 2.4 associated injuries for every facial fracture present in a patient suffering a motorcycle crash.

INITIAL EVALUATION

- 3 Although maxillofacial injuries can be visually distracting to the trauma team members, they must not cause deviation from

the established Advanced Trauma Life Support (ATLS) protocols. Rarely is facial trauma itself directly life threatening; however, as mentioned earlier, it should be viewed as a strong indicator of a significant mechanism of injury with associated injuries. Within the ATLS algorithms, there are considerations specific to maxillofacial injuries.

Airway Management

Airway compromise in maxillofacial injuries can result from direct laryngeal injury, foreign bodies (including aspirated teeth and bone fragments), or active bleeding from an upper airway source. Treatment of the compromised airway is complicated by the likelihood that 10% of facial trauma patients have cervical spine injuries.⁷ As initial treatment, any blood clots should be suctioned from the oropharynx, and a finger sweep used to remove foreign material from the oral airway. Comminuted fractures of the mandible can lead to loss of support of the hyomandibular complex and consequent ptosis and retroposition of the tongue. Manual anterior traction on the mandible symphysis will often temporarily resolve this obstruction until definitive control of the airway can be achieved.

For definitive control of the airway, an artificial oral or nasal airway is often possible, but the use of blind nasal intubation should be carried out with caution. Nasal intubations can exacerbate bleeding from the nasal and nasopharyngeal regions, and the tube may be inadvertently placed into the cranial fossa in the obtunded patient with a comminuted skull base fracture. In the case of severe maxillofacial injuries such as a gunshot wound to the face, intubation is often easier than expected, since the missing or pathologically mobile jaws allow an unprecedented view of the glottis. As with all facial trauma patients, those with significant maxillofacial injury should have a secured airway early in the trauma assessment. The secondary swelling that occurs over the first few hours following the trauma can impede, or in some cases prevent, oral intubation.

Emergent tracheotomy is rarely indicated except in the unusual circumstance of laryngeal fracture or the inability to intubate orally due to massive bleeding or swelling. Semielective tracheostomy in the operating room is reserved for those cases with expected prolonged intubation due to massive soft tissue and bony injuries or impaired consciousness.

Massive Hemorrhage

The elaborate vascularity of the head and neck can result in rapid significant blood loss. Fortunately, the location of the injuries allows sufficient access for direct pressure to control the hemorrhage. Efforts should be made when possible to expose and visualize the source of bleeding prior to suture ligation or cautery in order to avoid collateral damage to adjacent structures, primarily neural structures.

Nasopharyngeal bleeding is common in maxillofacial injuries. The blood supply to the nose arises from both the internal and external carotid systems. The external carotid artery supplies the internal maxillary artery, whose sphenopalatine branch supplies the posterior nasal septum and lateral nasal walls, and the facial artery, whose superior labial branch supplies the anterior inferior nasal cavity. The internal carotid artery gives off the ophthalmic artery, which in turn supplies the anterior and posterior ethmoidal arteries that perfuse the superior and anterior nasal septum. The most common site of epistaxis is at the Kiesselbach plexus at the confluence of the anterior ethmoidal and superior labial arteries. Anterior bleeding is best controlled by formal anterior nasal packing of half-inch gauze coated with antibiotic ointment. The tail of the gauze is left exposed, and with the aid of a nasal speculum, good lighting, and bayonet forceps, the gauze is carefully layered and packed back and forth along the nasal floor until the roof is reached. The direction of packing is directly posterior, then inferior. Prefabricated nasal packing is also available.

Posterior nasal bleeding, such as from the sphenopalatine artery, requires posterior packing. A 16- or 18-French Foley catheter is inserted into the nasopharynx through the nostril. The balloon is then inflated and pulled anteriorly against the vomer and posterior soft palate. The catheter is secured in this position with a clamp at the nostril. A rolled gauze is used to protect the columella from pressure necrosis. Posterior packing will stop the posterior bleeding from draining into the airway, but will divert the flow of blood anteriorly out the nose. The posterior packing must therefore be augmented with anterior packing.

Surgical ligation of the external carotid artery will not control bleeding from its injured branches due to the robust collateralization present. Selective ligation, such as of the ethmoidal vessels through a radix incision or of the internal maxillary artery through a Caldwell-Luc incision, is possible but rarely feasible in the emergency department. If the patient is stable enough to undergo a general anesthetic, the most effective way to address bleeding that is not controlled by packing is through reduction and rigid fixation of the fractures.

Recalcitrant bleeding is treated by angiographic embolization. The source vessels are identified angiographically and then occluded with embolization material such as Gelfoam. At Harborview Regional Medical Center in Seattle, from 1985 to 2000, of the 62,366 trauma cases, 7,147 had craniofacial trauma. During this same period, of the 3,529 cases of radiographic embolization, only 4 were performed on patients with craniofacial trauma. This emphasizes that although radiographic embolization is a component of the treatment algorithm of maxillofacial bleeding, the vast majority of cases can be treated with other means.⁸

Ocular Injury

Direct injury to the eyeball should be suspected in all patients with orbital fractures or lacerations to the periorbital region. One prospective study reported a 29% incidence of ocular injury in 49 patients with orbital fractures.⁹ Pain, decreased vision, and the appearance of spots before the eyes are all highly suggestive of globe damage. During the neurologic phase of trauma assessment, a brief clinical ophthalmologic examination should be performed. This would include visual acuity, pupillary response to light and accommodation, extraocular range of motion, globe position, and turgor. If there are any abnormal findings on the examination, an immediate ophthalmologic consult should be obtained for examination of the retina and ocular pressures. Injuries that may require immediate ophthalmologic treatment or result in permanent sequelae include corneoscleral lacerations, lens dislocation, major hyphema, acute glaucoma, and retinal detachment.

Blindness at the time of presentation is fortunately rare, but is an extremely poor prognostic factor for future sight. Patients with light perception at the time of presentation but who then demonstrate progressive loss of vision during the trauma assessment must be treated aggressively. The most common etiology of this presentation is traumatic optic neuropathy secondary to optic nerve compression from a retrobulbar hematoma, a bone fragment, or edema. The management of progressive vision loss remains controversial, for it is unclear which patients benefit from emergent optic nerve decompression. If the eyeball is tense, then immediate lateral canthotomy is indicated to release the confining force of the lids. If there is a clear source of compression visualized on computed tomography (CT), immediate operative decompression is indicated.¹⁰ All other patients are treated with high-dose steroids.¹¹

Cerebrospinal Fluid Rhinorrhea

Cerebrospinal fluid (CSF) leaks should be actively searched for in patients with craniofacial or high maxillary fractures. Clear

or serosanguineous nasal discharge, anosmia, or a salty taste in the mouth is highly suggestive. A CSF leak into the nasal cavity implies a defect in the pia-arachnoid and an abnormal communication between the subarachnoid space and the external environment. The thin bone in the anterior skull base and the close adherence of the dura to the anterior fossa and cribriform plate predispose to penetration of fracture fragments into the subarachnoid space. Common associated fracture patterns that are detailed later in the chapter include LeFort II and III midface fractures, naso-orbital ethmoid (NOE) patterns, orbital roof fractures, and displaced fractures of the posterior table of the frontal sinus. CSF is differentiated from serum on laboratory examination by its low protein concentration and from normal nasal secretions by the presence of glucose but no mucin.

Most CSF fistulas close spontaneously. Morgan et al.¹² reported a 35% incidence of CSF rhinorrhea in 300 patients with severe facial fractures, of which 66% resolved spontaneously by the fifth postinjury day, and 87% by the 10th day. Fistulas that do not close spontaneously can be visualized on a metrizamide contrast CT scan, followed by surgical exploration and obliteration of the fistula using a dural patch.

Occlusion

Occlusion is the contact of the posterior masticating (chewing) and anterior incising (cutting) surfaces of the maxillary and mandibular teeth. Malocclusion is an indicator of orthognathic fracture and/or dental injury. The maxillary teeth should overlap the mandible teeth in normal occlusion in three ways: (a) overjet describes the horizontal projection of the upper front teeth in front of the lower teeth, (b) overbite describes the vertical overlap of the upper front teeth over the lower teeth, and (c) the posterior maxillary arch should be wider than the mandible arch on both sides by the space of one cusp. Typical malocclusion patterns seen following fractures include an anterior open bite (gap between the upper and lower front teeth), that indicates the fractured maxilla is impacted upward or that both condyles of the mandible have collapsed; a posterior open bite (gap between the upper and lower back teeth) often associated with a unilateral condylar fracture; or a posterior cross-bite (back teeth lateral or medial to the normal arch form) that indicates either a mandible fracture or a comminuted fracture of the maxilla and palate. These malocclusion patterns indicate that surgical intervention is indicated.

Missing or fractured teeth should be documented. If a tooth is missing, the oral cavity and airway should be carefully checked for the foreign body. Securing the tooth to an adjacent one with a wire can often salvage a loose or dislocated tooth. If a tooth is fractured with unstable fragments, the fragments should be removed to prevent entrance into the airway.

Neurologic Injury

Injury to the muscles of facial expression or the seventh cranial nerve can be particularly debilitating, due to their importance in interpersonal interactions. The most common cause of facial nerve injury is fracture of the temporal bone in the intraosseous canal.¹³ Penetrating injury to the facial branches of the seventh nerve requires exploration and repair, whereas nonpenetrating injury is observed for recovery over a period of 3 to 6 months. Injury to the middle branches of the nerve distal to the parotid (zygomatic and buccal) can be masked by cross-innervation with other branches. The marginal mandibular (lower lip depressors) and temporal (brow elevation) branches have the least degree of cross-innervation, and therefore more commonly result in functional problems.

COMPUTED TOMOGRAPHY DIAGNOSIS OF MAXILLOFACIAL FRACTURES: THE FACIAL BUTTRESSES

The functional units of the face are held together and stabilized by several vertical and horizontal skeletal buttresses (Fig. 20.1). These buttresses represent regions of relatively dense bone that serve to support the functional units of the face in an optimal relation and define the form of the face by projecting the overlying soft tissue envelope.¹⁴ Additionally, the facial buttresses stabilize the face to the cranial base and determine the proper relationship between these two important structural units. Conceptualizing and describing maxillofacial fractures according to the involved buttresses is useful because they are directly related to the definitive surgical treatment. Each buttress can be visualized on the craniofacial CT scan. There are four transverse and four paired vertical buttresses. Due to the reliance of facial form and function on these buttresses, as well as the mechanical force exerted on them, the craniofacial trauma surgeon typically treats any significant buttress displacement using anatomic reduction and rigid internal fixation.

As structural units that support the face, the buttresses must either directly or indirectly interface with the skull base or cranium as a stable reference. From superior to inferior, the **transverse facial buttresses** are as follows:

1. *Upper transverse maxillary buttress* runs from the temporal bone across the zygomatic arch and inferior orbital rim, superiorly to the frontal bone via the frontal process of the maxilla, and then across to the contralateral temporal bone via a similar path. This buttress crosses the zygomaticotemporal, the zygomaticomaxillary, and the nasofrontal sutures,

which are commonly involved in fracture patterns. The sagittal extensions of this buttress are the orbital floors.

2. *Lower transverse maxillary buttress.* From the pterygoid projection of the skull base, it extends along the bone of the maxillary alveolar arch to the contralateral pterygoids. The sagittal extension of this buttress is the hard palate.
3. *Upper transverse mandibular buttress* is at the level of the mandible's alveolar arch.
4. *Lower transverse mandibular buttress* is at the inferior border of the mandible.

The **paired vertical buttresses** from lateral to medial are as follows:

1. *Posterior vertical mandibular buttress.* Composed of the ascending ramus and condyle of the mandible, this buttress links the transverse mandibular buttresses with the skull base.
2. *Lateral maxillary buttress* is composed of the column of bone from the alveolar bone of the posterior maxillary molars across the zygomaticomaxillary suture and body of the zygoma, extending superiorly to the lateral orbital rim and across the zygomaticofrontal suture. The sagittal projection of this buttress includes the lateral orbital wall as it joins the sphenoid bone of the skull base.
3. *Medial maxillary buttress* is composed of the column of bone from the alveolar bone of the anterior maxillary dentition, extending superiorly along the rim of the piriform aperture and frontal process of the maxilla, then across the nasofrontal junction to frontal bone. The sagittal projection of this buttress includes the medial orbital wall.
4. *Posterior maxillary buttress* is composed of the column of bone at the pterygomaxillary junction where the pterygoid plates of the sphenoid join the posterior maxilla. These last three vertical buttresses support the transverse buttress of the maxillary occlusion.

Although other anatomic buttresses of the face can be conceptualized, the ones listed here meet the following critical criteria: (a) they are all linked either directly or through another buttress to the cranium or cranial base as a stable reference point, (b) they have sufficient bone thickness to accommodate metal screw fixation, and (c) with the exception of the posterior maxillary buttress, they are surgically accessible through standard limited surgical incisions. Accurate reduction and fixation of these facial buttresses restores projection, width, and height of the facial skeleton relative to the cranial base and, more important, establishes a functional support for the teeth and globes.

PATTERNS OF INJURY

Naso-orbito-ethmoid Fractures

NOE fractures involve the central upper midface between the eyes, disrupting the confluence of the medial maxillary buttress with the upper transverse maxillary buttress. Fractures of the NOE complex can be one of the most difficult fracture patterns to accurately repair. Failure to restore the sagittal projection of this region and correct the rotation of the frontal process of the maxilla (superior portion of the medial maxillary buttress) will result in a lack of upper nasal projection and telecanthus (increased distance between the inner corner of the eyes), both of which are difficult to correct as a secondary operation. The eyelids insert around the lacrimal fossa through the medial canthal tendon. If the tendon insertion is not returned to its correct position, the patient loses the normal shadow definition on either side of the nose, the medial corner of the palpebral fissure drifts laterally, and the eyes appear too far apart. If the distance between the medial canthi is greater than 30 mm, a NOE pattern should be suspected.

By definition, NOE fractures include damage to the ethmoid sinus and walls. If there is bilateral comminution and

displacement in this region, the nasofrontal ducts that drain the frontal sinus are also likely disrupted. In this situation, the surgeon obliterates the frontal sinus by removing all of the sinus mucosa and filling the sinus with bone, fat, or some other tissue. Failure to diagnose disruption of the nasofrontal ducts and obliterate the sinus increases the risk of developing a frontal sinus mucocele postoperatively.

Zygoma and Orbital Fractures

Following nasal fractures, zygomatic fractures are the most common injury resulting from blunt trauma. The zygoma has two attachments to the cranium and two to the maxilla and forms a large portion of the orbital floor and lateral wall. These paired “cornerstone” bones are therefore surgically important in establishing orbital volume and in serving as a reference for maxilla reduction in LeFort-type maxillary fractures. The two major buttresses of the zygoma are the upper transverse maxillary (across the zygomaticotemporal and zygomaticomaxillary sutures) and the lateral vertical maxillary (across the zygomaticomaxillary and frontozygomatic sutures). Fractures typically occur across these three buttress-related sutures, leading to the term *tripod fracture*. This term fails to recognize the posterior relationship of the zygoma with the sphenoid bone of the skull base. A displaced orbitozygomatic fracture is really a quadripod fracture. If the two buttresses of the zygoma are reduced and fixated, it is still possible to have a rotational deformity of the zygoma about the zygomaticosphenoid suture. The surgeon pays particular attention to the alignment of the zygoma and sphenoid at the lateral orbital wall, since angulation here after fixation of the remaining buttresses reflects a residual rotational deformity and an associated increased orbital volume.

If the zygomatic arch component of the transverse buttress is comminuted and is needed as a reference to establish facial projection following a panfacial injury, the only way to access this region is via the coronal scalp degloving approach, which carries with it an associated increased blood loss, operating time, and risk for potential complications.

Orbital floor fractures can occur in isolation but are also commonly associated with zygoma fractures through posterior propagation of the fracture from the upper transverse maxillary buttress at the inferior orbital rim. The size and displacement of the orbital floor fragment must be known preoperatively to decide what treatment, if any, is required. The width of the defect of the floor can be estimated from the coronal reformat images, and the depth by counting the number of coronal cuts containing the fracture. Multiplying these two gives an estimate of the area of the defect. Attention to the shape and position of the inferior rectus muscle on the coronal CT scan can provide information regarding the damage to the fascial sling of the globe. If the rectus remains flattened on cross section and in the correct position, the surgeon will likely encounter minimal entrapped periorbital tissue. If, however, the inferior rectus is round and inferiorly displaced, the fascial sling is disrupted and the periorbital and muscle have prolapsed into the orbital floor defect (Fig. 20.2A). Entrapment of the inferior rectus in children can be easily missed because the flexible bone can spring back in place like a trapdoor, looking normal on CT scan except for the entrapped muscle beneath it (Fig. 20.2B). This trapdoor fracture requires urgent treatment within 24 to 72 hours to minimize the chance of motility problems.¹⁵

Maxillary Fractures

With the exception of alveolar and palate fractures, maxillary fractures are commonly described according to the classification described by Rene LeFort in 1901¹⁶ (Fig. 20.3). LeFort fractures involve a separation of all or a portion of the maxilla

FIGURE 20.2. Computed tomography coronal plane noncontrast images demonstrating two patterns of orbital floor blowout fractures. **A:** A left orbital floor fracture with evidence of entrapment of the inferior rectus muscle. The inferior rectus (arrow) is displaced inferiorly into the maxillary sinus. Note how the muscle cross section has changed from ovoid to circular. The fascial support has been disrupted and the muscle is entrapped. **B:** A pediatric trapdoor left orbital floor blowout fracture. The orbital floor was disrupted by the impact, but then sprung back in place, trapping the inferior rectus muscle (arrow) within the maxillary sinus. Since the bone has returned to its anatomic location, this diagnosis can easily be missed unless attention is paid to the location of the extraocular muscles. Trapdoor fractures require emergent treatment to optimize the chance of recovery.

from the skull base. For this to occur, the posterior vertical maxillary buttress at the junction of the posterior maxillary sinus with the pterygoid plates of the sphenoid must be disrupted. This can either be through the posterior walls of the sinus or through the plates themselves as seen on axial CT images. Once a pterygomaxillary disjunction has been diagnosed, the remaining facial buttresses are inspected to determine the class of LeFort fracture. If the inferior portions of both the lateral and medial maxillary buttresses are fractured, a LeFort I fracture has occurred, and the maxillary arch (lower transverse maxillary buttress) will move in relation to the rest of the face and skull. If the inferior lateral maxillary buttress (zygomaticomaxillary suture) and the superior medial maxillary buttresses (frontomaxillary sutures) are fractured, then the entire maxilla will move in relation to the skull base as a LeFort II fragment. If the upper transverse (zygomatic arch), superior lateral (frontozygomatic), and superior medial (maxillofrontal) maxillary buttresses are fractured, then craniofacial separation has occurred as a LeFort III pattern, with the entire face moving in relation to the skull base.

For all LeFort fractures, the maxillary dental arch is mobile; therefore, the patient must be placed in maxillo-mandibular fixation prior to plating of the fractures. All buttresses can be plated with the exception of the buttress common to all LeFort patterns—the pterygomaxillary posterior vertical buttress. Similar to zygomatic fractures, if there is severe comminution of a buttress, bone grafting may be required.

FIGURE 20.3. Computed tomography coronal plane noncontrast image demonstrating bilateral LeFort I, II, and III fractures in the same patient. The LeFort I pattern has fractures through the inferior portions of the medial and lateral maxillary buttresses, the LeFort II pattern is through the zygomaticomaxillary and frontomaxillary sutures, and the LeFort III pattern is complete craniofacial dissociation. To confirm the diagnosis, pterygomaxillary disjunction and fractures of the zygomatic arches would need to be observed on axial plane images.

Mandible Fractures

Unlike the rest of the facial buttresses, isolated mandible fractures are typically diagnosed with plain radiograph series. In a trauma patient with multiple injuries, however, the diagnosis is often made on CT scan imaging as a disruption of the mandible arch. Fractures can occur at any point on the mandible including, in decreasing order of frequency, the body, angle, condylar neck, symphysis and parasymphysis, ramus, and alveolar ridge. The condyles are best visualized on coronal images. Many condylar fractures are not directly fixated because of the difficulty accessing this region surgically as a result of the proximity of the facial nerve, as well as the risk of iatrogenic temporomandibular joint (TMJ) dysfunction. If there are bilateral condylar neck fractures associated with a severely comminuted LeFort fracture, one condyle is typically exposed, reduced, and plated in order to reestablish a stable vertical buttress for reestablishing facial height. Intracapsular condylar injuries have a high risk of ankylosis and are treated conservatively with early range of motion if occlusion can be established.

TIMING OF DEFINITIVE REPAIR

There are two windows for optimum treatment of maxillofacial injuries. The first is in the first 6 to 12 hours following injury, before the onset of edema. With the exception of emergencies such as optic nerve compression, uncontrollable facial bleeding, or pediatric trapdoor orbital fractures, this phase is not feasible in a multisystem trauma victim due to the priority

of other injuries. The most common timing for maxillofacial injuries is after the initial postinjury edema has subsided and the patient is cleared for the operating room. This is typically 3 to 7 days postinjury. Although facial fractures can be reduced up to 3 weeks postinjury, the soft tissue fibrosis and the early fracture callus make the procedure progressively more difficult starting 10 days after the injury. Mandible fractures have been traditionally treated as open fractures, with definitive treatment within 24 hours.

SUMMARY

Maxillofacial injuries in a trauma victim should be considered an indicator of associated severe injuries. The initial evaluation within the ATLS protocol includes special considerations of airway management, ocular assessment, control of bleeding, identification of CSF leaks, and neurologic injury. The definitive treatment of maxillofacial injuries, following a structured history and physical examination, includes identification of damage to the facial buttresses on CT imaging. Displaced buttress fractures require open reduction and internal fixation in a timely fashion to minimize secondary soft tissue contracture and optimize the final functional and esthetic outcome.

CHAPTER 21 ■ NECK INJURIES

SAMAN ARBABI

KEY POINTS

- The numerous vital structures in the neck are concentrated in a small anatomic area at risk of injury, unprotected by bone or dense muscular covering.
 - Anatomically, in addition to large bilateral anterior and posterior triangles, the anterior neck is divided into three zones: zone I, extending from the sternal notch to the cricoid cartilage; zone II, from the cricoid cartilage to the angle of the mandible; and zone III, from the angle of the mandible to the base of the skull.
 - Mechanism and anatomic location of trauma are frequently predictive of pattern and number of vital structures injured.
 - Mandatory versus selective exploration of a penetrating neck injury is determined by anatomic and physical findings in addition to local resources and physician capabilities.
 - Patterns of fractures of the face, skull, and neck, along with significant soft tissue trauma and subcutaneous emphysema, predict the likelihood of airway or vascular injury, with computed tomography angiography being the most appropriate screening diagnostic test.
- The numerous vital structures of the neck are concentrated in a small anatomic area, generally unprotected by bone or dense muscular covering. Yet, because of its relatively small size, only 5% to 10% of traumatic injuries involve the neck. Although neck injuries occur infrequently, they often require prompt surgical management. Disruption of the airway or carotid circulation is an immediate, life-threatening problem, and esophageal or peripheral nerve injury can cause chronic morbidity. Penetrating injuries are most common and most severe, with fatality rates ranging from 1% to 2% for stab wounds, from 5% to 12% for gunshot wounds, and up to 50% for rifle or shotgun blasts.^{1–3} Up to 50% of these deaths are preventable with appropriate early care. Significant blunt neck trauma is less common but can be particularly difficult to manage because it often involves the airway. Carotid or vertebral artery injury can also occur as a consequence of acute cervical spine hyperextension, even in the absence of bony injury. The initial diagnosis of these injuries can be difficult, yet the consequences of missing an injury are severe.
- As a general guideline, all patients with penetrating neck wounds that traverse the platysma muscle should be admitted to the hospital for evaluation, observation, and treatment. Likewise, all patients with blunt traumatic injuries of the neck should be admitted. This section of the text focuses on the

FIGURE 21.1. Anatomic triangles of the neck. The posterior triangle is composed of the smaller occipital and omoclavicular triangles. The anterior triangle has as smaller divisions the carotid, muscular, submandibular, and suprahyoid triangles.

available and preferred diagnostic and treatment options for patients with blunt or penetrating neck trauma.

ANATOMY

- 2 The neck is classically divided into a number of anatomic triangles (Fig. 21.1). The two large anterior and posterior triangles are particularly important in neck trauma. Wounds to the

posterior triangle rarely involve the esophagus, airway, or major vascular structures, although if the blow is directed inferiorly, intrathoracic injury can occur. In contrast, penetrating wounds that enter through either the sternocleidomastoid muscle or the anterior triangle carry a high likelihood of vascular, airway, or esophageal injury (Fig. 21.2).

The anterior neck is further divided into three zones defined by horizontal planes. Zone I represents the base of the neck and is variably defined. In the Roon and Christensen classifi-

FIGURE 21.2. Proximity of cranial nerves to the carotid arteries of the neck. Trauma resulting in cranial nerve deficits in this region is often associated with vascular injury.

FIGURE 21.3. Zones of the neck. The junction of zones I and II is variously described as being at the cricoid cartilage or at the top of the clavicles. The important implication of a zone I injury is the greater potential for intrathoracic great vessel injury.

cation,⁴ zone I is defined as extending from the sternal notch to the lower border of the cricoid cartilage (Fig. 21.3). Injuries here carry the highest mortality rate because of the risk of major vascular and intrathoracic injury. Zone II is the central and largest portion of the neck. It extends from the top of zone I to the angle of the mandible. Zone II injuries are most common but carry a lower mortality rate than either zone I or III injuries, because injury is usually apparent and exposure of vital structures is readily accomplished. Zone III is that part of the neck above the angle of the mandible. The risk of injury to the distal carotid artery, salivary glands, and pharynx is greatest in this zone. Exposure in this region can be particularly difficult.

The other major anatomic landmark in the neck is the platysma muscle. This thin, broad muscle lies just beneath the skin and covers the entire anterior triangle and anteroinferior aspect of the posterior triangle. Wounds that fail to penetrate the platysma are considered superficial and do not warrant extensive evaluation. Wounds that penetrate the platysma must be considered a serious surgical problem that mandates hospital admission and further evaluation.

INITIAL MANAGEMENT

The same priorities for initial care of the multiply injured patient apply to the management of isolated neck trauma. Airway control remains the primary tenet of initial trauma care, and it takes precedence over all other aspects of the evaluation and resuscitation. If injury involves the airway itself or surrounding structures, this management task takes on special significance. Rapid inspection for air movement, crepitus, hoarseness, and subcutaneous emphysema is the first step. Supplemental oxygen should always be administered, and adequate lighting and suction are essential. If spontaneous ventilation appears adequate, close observation and pulse oximetry monitoring are suggested, because acute decompensation can occur with little warning. If spontaneous respirations are inadequate, if blood or other material obstructs the airway, or if progressive cervical swelling from hemorrhage threatens to occlude the airway, emergency intubation is necessary. Procrastination converts a simple intubation into a difficult and bloody emergency tracheostomy. Direct visualization of the vocal cords and oral endotracheal intubation are usually pre-

ferred. If cervical spine injury has not been excluded, hyperextension of the neck must be avoided. Two-man intubation with in-line cervical traction is the preferred alternative to nasotracheal intubation.

A massive pharyngeal or neck hematoma can totally occlude the airway, making direct intubation impossible. Attempts at blind nasotracheal intubation can further aggravate mucosal or laryngeal injury, and an emergency surgical airway (cricothyroidotomy or tracheostomy) is required. Occasionally, blunt laryngeal trauma is so severe as to disrupt and occlude the airway. The preferred method of controlling the airway in this setting is controversial, but provisions for a surgical airway must be at hand. Options include primary tracheostomy or a single attempt at endoscopically assisted endotracheal intubation. Temporization with transtracheal needle-jet insufflation can be a valuable adjunct in these settings, and mandatory in the young child.

Concurrent with airway control is awareness of potential cervical spine injury, particularly in unconscious patients who have sustained blunt head and neck trauma. The head and neck should be supported in the neutral position until this possibility is excluded radiographically and by physical examination. In the emergency room, support of the head and neck during manipulation or procedures is best accomplished by a strong, steady assistant rather than by collars, sandbags, or tape. The lateral cervical spine film is an essential component of the initial evaluation of patients with either blunt or penetrating neck trauma, both to assess the bony cervical spine and to evaluate soft tissues for edema or malplaced air.

The initial management subsequent to control of the airway follows the ABC guidelines of trauma care advocated by the Advanced Trauma Life Support course of the American College of Surgeons, with particular attention directed at adequacy of ventilation, treatment of shock, and baseline neurologic examination. Patients with blunt neck trauma often have concomitant thoracic injuries, and penetrating neck wounds may follow a caudal trajectory, injuring lung or intrathoracic great vessels, particularly if the entrance is in zone I.⁵ Rapid physical examination of the thorax is therefore part of the initial evaluation of neck trauma patients and should include inspection, palpation, and auscultation. Pneumothorax must be treated rapidly by needle decompression or tube thoracostomy, or both, and treatment should not necessarily be delayed for radiographic confirmation, particularly in the unstable patient. Major neck hemorrhage is treated with direct pressure. Blind clamping of vessels is discouraged to avoid inadvertent injury to adjacent nerves or esophagus. Adequate peripheral intravenous access is required in all patients with neck trauma and usually requires at least two peripheral intravenous catheter lines of 16 gauge or larger contralateral to the side of greatest neck injury. Blood is drawn for typing and cross matching and routine laboratory evaluations, and fluid resuscitation is initiated based on the degree of shock and anticipated hemorrhage. A rapid yet thorough neurologic examination is also part of the initial management, with particular attention to the patient's level of consciousness and the status of cranial and brachial plexus nerves. Changes in the results of neurologic examination are key indicators of progressive injury.

3 After the initial resuscitation, a complete physical examination is performed to detect associated injuries and to better define the extent of neck trauma. Close visual inspection of the neck alerts the physician to the possibility of underlying injuries and the mechanism of injury. For example, an oblique 4- to 6-cm bruise on the neck of a restrained passenger in a motor vehicle accident should alert the physician to the possibility of blunt cervical vascular trauma from a seat belt injury. Neck wounds should not be probed for fear of dislodging a clot and reinstituting hemorrhage. The neck should be palpated with attention to normal anatomic landmarks and areas of tenderness. Crepitus or subcutaneous emphysema indicates

TABLE 21.1 **DIAGNOSIS**

CLINICAL SIGNS OF SIGNIFICANT INJURY IN PENETRATING NECK TRAUMA

■ VASCULAR	■ DIGESTIVE TRACT
Shock	Hemoptysis
Active bleeding	Dysphagia or odynophagia
Large or expanding hematoma	Hematemesis
Pulse deficit	Subcutaneous emphysema
■ AIRWAY	■ NEUROLOGIC
Dyspnea	Focal or lateralized neurologic deficit
Stridor	
Hoarseness	
Dysphonia or voice change	
Subcutaneous emphysema	

injury to the trachea, esophagus, or lung until proven otherwise. Never assume that a penetrating skin wound itself is responsible for subcutaneous air. If the patient is able to talk, determine the presence of hoarseness, dysphagia, or dysphonia. Hemoptysis and hematemesis are also signs of tracheal or esophageal injury. Table 21.1 lists the clinical signs of significant injury that usually mandate neck exploration to exclude or treat vascular, airway, esophageal, or nerve injuries.

All patients with blunt or penetrating neck trauma should have a chest radiograph to rule out thoracic trauma. Stable patients should have soft tissue neck films to look for retropharyngeal hematoma, tracheal narrowing or deviation, retained missile fragments and pathways, and subcutaneous or retropharyngeal air. Computed tomography (CT) of the neck is particularly helpful in blunt trauma to evaluate laryngeal structures to look for laryngeal fractures. Patients with blunt neck trauma whose neurologic examination is inconsistent with findings on head CT should undergo studies to evaluate for cervical vascular injury.

SELECTIVE VERSUS MANDATORY EXPLORATION

There is uniform agreement that all unstable patients and all patients with clinical signs of significant neck injury require prompt exploration. All other patients with wounds that penetrate the platysma should at least be admitted to the hospital and observed. Controversy exists, however, in the management of asymptomatic, stable patients with penetrating neck injury. Two distinct schools of thought exist, one advocating mandatory surgical exploration of all wounds that penetrate the platysma^{2,6,7} and the other favoring a more selective approach.⁸⁻¹² A comprehensive review of selective versus mandatory operative management published in 1991 documents similar rates for injury incidence, overall mortality, and delayed complications, as well as similar hospital costs, but with a significant reduction of negative neck explorations in the selective management group¹³ (Table 21.2). Most recent studies have advocated some type of selective management in a clinical setting with explicit guidelines and expertise in the appropriate use of various diagnostic modalities.¹⁴⁻¹⁷

Advocates of a mandatory exploration policy cite the low morbidity and negligible mortality rate after negative neck exploration as justification for the high rate of negative findings

TABLE 21.2

MANDATORY OPERATION COMPARED WITH SELECTIVE MANAGEMENT OF PENETRATING NECK TRAUMA

	■ MANDATORY	■ SELECTIVE
Patients		
Number of series	11	24
Number of patients	1,653	2,540
Outcome		
Mortality rate (range)	5.85% (0.3%–11.0%)	3.75% (0%–9.8%)
Cases explored	1,492 (90.2%)	1,596 (62.8%)
Positive explorations	803 (53.8%)	1,117 (70.0%)
Cases observed	161 (9.8%)	944 (37.2%)
Delayed exploration	3 (1.9%)	20 (2.1%)
System injured		
Arterial injuries	213 (12.9%)	303 (11.9%)
Venous injuries	310 (18.8%)	459 (18.0%)
Esophagus or pharynx	163 (9.9%)	191 (7.5%)
Larynx or trachea	150 (9.1%)	181 (7.1%)

Modified from Asensio J, Valenziano C, Falcone R, et al. Management of penetrating neck injuries: the controversy surrounding zone III injuries. *Surg Clin North Am* 1991;71:267.

(40% to 60%). The disastrous complications of missed injuries further support this stance. A 67% mortality rate is reported after delayed operations for neck vascular injuries, and a 44% mortality rate for delayed operations for esophageal injuries.³ A 1986 literature review reported an overall mortality rate of 16.7% for patients initially observed after penetrating neck trauma who subsequently required surgical exploration.¹⁸ In addition, a few reports have documented major structural injury in a small percentage of patients who undergo exploration despite a clinically silent physical examination; in one report, 5.5% of patients with wounds that appeared innocuous but were nevertheless explored had significant injuries.⁷ Transcervical gunshot injuries represent a special category of neck wounds, with one report documenting the high likelihood of injuries to cervical structures (83%) and supporting aggressive surgical exploration in all cases.¹⁹

Supporters of a more selective approach berate the high incidence of negative explorations, the cost of a surgical exploration, and the fact that some injuries are missed in spite of a surgical exploration. They also argue that the original data supporting mandatory neck exploration are based on World War II and Vietnam War experience with large-caliber, high-velocity projectiles, unlike the typical knife or hand gun injury observed in civilian trauma. The wide availability and diagnostic accuracy of angiography, endoscopy, and esophagography further support a selective management plan. Merion et al.,¹² as part of a review of the cost of managing penetrating neck trauma, analyzed 27 reported series in which the clinical courses of more than 4,000 patients with penetrating neck trauma were documented. Of patients treated by surgeons advocating selective exploration, 52% underwent immediate operation, compared with almost 90% of patients treated by those advocating mandatory exploration. Reexamination of these series revealed that mortality rate was no different in the two groups, and only 2.4% of initially observed patients required subsequent operation.¹⁸

No uniform policy has been adopted for selective management of penetrating neck injury patients in the absence of positive clinical findings. There is general agreement that zone I and III injuries require diagnostic studies such as helical CT angiography, angiography, endoscopy, and esophageal contrast studies.²⁰ The management of zone II injury, however, is variable and subject to the experience and preference of individual surgeons and trauma centers.^{14–17} The disagreement concerns whether patients should routinely undergo surgical neck exploration, undergo extensive diagnostic evaluation similar to zone I and III injuries, or simply be observed. With the evolution of helical CT angiography (CTA), however, most recent studies support some kind of selective management of stable patients with penetrating neck injuries. A single-center study, evaluating stable penetrating neck trauma patients during a 16-month period, demonstrated helical CTA to have 100% sensitivity and 93.5% specificity in detecting all vascular and aerodigestive injuries sustained.²¹ In some trauma centers, CTA has replaced conventional angiography in the initial assessment of stable penetrating trauma patients, since CTA is less costly and faster, does not require assembly of an angiographic team, and has fewer potential complications.²² Angiography still remains the “gold standard” and is performed in patients who have inadequate studies, streak artifacts due to foreign bodies, or inconclusive CTA results. Performing diagnostic tests, such as endoscopy and esophageal contrast studies, in addition to CTA, is controversial. The accuracy of helical CT scan in detecting esophageal injury has not been studied extensively. In one study, two (50%) of four esophageal injuries in patients with penetrating trauma were missed by CT. It is important to note that esophagography missed the same two esophageal injuries as well.²³ The conclusion is that CT scan is no better or worse than esophagography in screening for esophageal injury. Further support for use of helical CT in penetrating trauma is the identification of the trajectory track. Such findings may increase suspicion of injury to the aerodigestive tract, thus delineating the need for observation, esophagoscopy, or operative exploration. Because a number of clinical reviews demonstrate similar patient outcomes, each institution or surgeon should adopt a management plan most consistent with local resources and experience.

At Harborview Medical Center in Seattle, all patients with neck wounds who are in hypovolemic shock or who have evolving stroke are immediately explored for vascular control. Most of those with neck wounds that penetrate the platysma in zone II undergo exploration, as do all patients with clinical signs of tracheal, esophageal, or major vascular injury. The track of the offending agent is followed throughout its course to exclude any possible vascular, tracheal, esophageal, or neurologic injury. Endoscopy is usually performed intraoperatively if pharyngeal, esophageal, or tracheal injury is suspected but cannot readily be identified. Some asymptomatic, stable patients with penetrating zone II neck injury are evaluated initially with CTA. Zone I and III penetrating injuries are selectively managed, based on clinical presentation and the results of diagnostic studies. Hemodynamically unstable patients undergo immediate exploration, with operative incision based on the most likely source of vascular injury. Zone I injuries are managed like mediastinal traversing wounds.^{19,24} CTA is performed in hemodynamically stable patients with penetrating wounds to zone I to identify potential injuries to the thoracic outlet vessels or to better plan the operative approach. Depending on the penetrating wound trajectory seen on CTA, esophagography is performed to detect esophageal injury. Endoscopy is considered a complementary procedure to the esophagography, and should follow if there is any question of an abnormality.²⁵ CTA is also performed for zone III injuries, because of the possible inaccessibility of internal carotid artery lesions or to demonstrate a need for systemic anticoagula-

tion. Angiography is performed in patients with inadequate or inconclusive CTA. In addition, most of the vascular lesions identified at the base of the skull are best managed by interventional angiography techniques.

Evolution in Diagnostic Modalities

Hemodynamically stable patients who sustain trauma with potential injury to the neck may be candidates for nonoperative management. Most of these patients lack the “hard” signs of injury such as expanding hematoma, active bleeding, significant air leak, or airway compromise.²⁶ These patients may be observed with assistance of diagnostic modalities when indicated. Traditionally, the most common studies are radiographic survey of the cervical spine, four-vessel angiography, esophagoscopy and/or esophagography, and bronchoscopy. Performing these studies, however, may be expensive and time consuming. In addition, four-vessel angiography is an invasive test with potential for complications. Therefore, a more selective approach to screen for cerebrovascular injuries is warranted and has been practiced.²⁷ Recently, with improvement of less invasive diagnostic methods such as helical CTA or magnetic resonance angiography (MRA), there has been an effort to substitute such modalities in place of routine angiography.^{28,29}

5 CTA offers definitive advantages and has emerged as the primary diagnostic screening modality.²⁶ In fact, high-resolution CTA has replaced angiography in evaluation of selected patients with potential for cerebrovascular injuries in some trauma centers. The allure for helical CT is that it is a relatively fast, noninvasive test that can evaluate cervical spine, trachea, soft tissue, and vascular structures at the same time. Earlier data demonstrated CTA to be inadequate for screening of patients with blunt neck injury.³⁰ The diagnostic accuracy of high-resolution helical CTA, however, has improved with advances in image technology and increasing experience and expertise in evaluating these studies in trauma patients. Helical CT technology is rapidly changing, and the single-detector row is being replaced with multidetector row configuration, generating 1-mm-thick sections that are reconstructed at 0.5-mm intervals.³¹ The recent data from the radiologic literature are favorable, reporting a sensitivity and specificity of 90% and 100%, respectively, in diagnosis of carotid and vertebral artery injuries in selected patients with penetrating neck injury.^{31–33} Four major published studies have concluded that 16-channel detectors can be used to accurately screen at-risk patients for blunt cervical vascular injuries.^{34–37} Eastman et al. compared digital subtraction angiography to CTA in a prospective study and identified 46 blunt cervical vascular injuries among 43 patients.³⁵ The overall sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of CTA for the diagnosis of blunt cervical vascular injuries were 97.7%, 100%, 100%, 99.3%, and 99.3%, respectively.³⁵ The accuracy of helical CT in detecting blunt cervical vascular injuries remains controversial, however. A recent prospective comparative study of 16-channel detector CTA and angiography for detection of blunt cervical vascular injuries in at-risk trauma patients demonstrated the sensitivity, specificity, positive predictive value, and negative predictive value of CTA to be 74%, 86%, 65%, and 90%, respectively.³⁸ In addition, although CTA is less invasive than traditional angiography, the volume of contrast material used for helical CTA may be higher.³³ This is especially true when a focused study of the unilateral carotid or vertebral artery is desired rather than four-vessel angiography. Therefore, a digital subtraction angiography may be preferred in patients with high risk for contrast-induced nephrotoxicity.³³ Further studies of helical CTA in evaluation of trauma patients are warranted before uniform acceptance of this diagnostic modality; however, with the arrival of 64-detector scanners and increased

experience with the technology, CTA is likely to replace angiography in screening for cervical vascular injuries.

There is encouraging evidence regarding the use of duplex ultrasound and MRA as screening diagnostic tools.^{39,40} In a multicenter study, duplex ultrasound demonstrated 86% (12 of 14) of the arterial injuries but was unable to discern dissection of the internal carotid artery at the base of the skull in two patients; proximal flow characteristics were also normal in both of these patients.^{39,41} Use of MRA in screening of trauma patients has been limited due to practical problems such as monitoring the patient in the magnetic resonance imaging suite and lack of around-the-clock access. Most data regarding evaluation of cerebrovascular structures by MRA are in nontrauma patients.^{42–44} In these studies MRA demonstrated a high accuracy in detecting vascular disease but remained less reliable than the “gold standard” digital subtraction angiography. The sensitivity of MRA in detecting cerebrovascular injuries in 143 blunt trauma patients was only 50%.³⁰ This study, however, utilized a 0.2 Tesla open magnet, and current studies utilize 1.5 Tesla magnets with significantly better image quality. Improving image quality and increasing experience in interpreting the findings may improve the accuracy of MRA in detecting cerebrovascular injury.

In the past, CT was frequently utilized to evaluate the cervical spine after incomplete or inadequate plain films. However, evaluation of the cervical spine for identification of fractures following blunt trauma has been changing from the traditional three-view plain film to helical CT scan with sagittal reconstruction. This is especially true in patients who require a CT scan of the head. Obtaining a helical CT scan of the cervical spine as the initial study has expedited time, as the initial study has expedited time to spine clearance,⁴⁵ increased sensitivity,⁴⁶ and decreased costs.⁴⁷

The combination of the aforementioned findings makes helical CT scan an ideal screening tool for neck injuries. One advantage of helical CTA is that it can be incorporated in the workup of a blunt trauma patient who is having a head CT scan to evaluate intracranial structures because of concomitant head injury. Ideally, the cervical spine, soft tissue, and vascular structures are evaluated, without extra trips to the plain radiology or angiography suite. Other modalities such as MRA do not have the versatility of the helical CT scan, require

the presence of around-the-clock expertise, still lack sufficient evidence to demonstrate their accuracy, and may possess high costs, all of which may make them impractical to use as mass screening tools for trauma patients.

OPERATIVE EXPLORATION

Of patients with penetrating neck trauma (depending on mechanism), 25% to 50% present with obvious signs of injury requiring prompt operation. An additional 10% to 20% of patients without clinical signs of injury are discovered to have significant vascular, esophageal, or airway injury on further diagnostic testing. A physician treating patients with neck trauma must be capable of performing a complete neck exploration and repair of vascular and aerodigestive injuries. Neck exploration should be performed in the operating room under general endotracheal anesthesia. In the hemodynamically stable patient with a patent airway, intubation can be deferred until laryngoscopy and bronchoscopy have been performed. A nasogastric tube is usually passed to ensure an empty stomach. Preparation and draping of the patient before induction of anesthesia allows control of hemorrhage if the patient starts to gag at the time of placement of the endotracheal tube. The chest is also auscultated before surgery, and a chest radiograph is routinely performed, because penetrating injuries may follow a downward path with pleural penetration. A pneumo-thorax may not develop until positive-pressure ventilation is applied, and it may initially present as unexplained hypotension during anesthesia.

The incision is planned to allow full exposure of the tract of the injury (Fig. 21.4). The oblique incision along the anterior border of the sternocleidomastoid muscle is preferred for unilateral and high (zone III) injuries, whereas the transverse collar incision is preferable for bilateral or neck-traversing wounds. Extension of either neck incision into a median sternotomy affords excellent exposure of the thoracic great vessels. Proximal and distal control of the major vessels potentially involved must also be considered in the length and position of the incision, and the patient is always surgically prepared for a possible median sternotomy. The tract of the injury is followed to its depth, systematically examining each structure in or near the tract.

FIGURE 21.4. Neck exploration incisions. Extension of oblique or collar incision into a median sternotomy affords excellent exposure of the great vessels.

MANAGEMENT OF SPECIFIC INJURIES

Blood Vessels

Blood vessels are the most commonly injured structures in the neck. Major arterial and venous injuries occur in 18% and 26% of penetrating neck wounds, respectively.⁴⁸ There has been an increase in reported blunt carotid injuries, most likely due to better recognition.^{49–51} Most recent studies report an incidence rate of 1% to 2% for blunt cervical vascular injuries. The initial diagnosis, however, remains a difficult one and must always be suspected with an appropriate mechanism of injury.

Carotid Artery

In one of the largest series reported in English literature, 85 blunt carotid injuries were recognized in 67 patients over 11 years in a level I trauma center.⁵¹ Motor vehicle crashes were the most common injury mechanism (82%), followed by motorcycle crashes (7%) and assaults (6%). All but two of the patients had associated injuries, and combinations of blunt carotid injury with closed head and cervical spine injuries occurred in 48% and 6% of patients, respectively. The initial physical examination demonstrated neurologic examination that was not compatible with brain CT in 34% and soft tissue injury in the anterior neck in 14% of the patients. A neurologic deficit developed subsequent to hospital admission in 43% of the patients. The average interval from injury to definitive diagnosis was 53 hours, highlighting the point that, although its recognition is often delayed, blunt carotid trauma must be suspected in patients who develop focal neurologic signs or symptoms after a latent interval. In a multicenter review, 29% of patients developed significant neurologic deficits more than 12 hours after admission.⁴¹ Other physical findings—expanding hematoma, audible bruit, pulsatile neck mass, palpable thrill, Horner syndrome, or any neurologic symptom not explained by other injuries—may be absent at the initial examination. Cervical vascular injury should be suspected in trauma patients with neurologic deficit not explained by head CT. Because some evidence suggested improved outcome with early diagnosis,^{41,50,51} a high index of suspicion must exist if the mechanism of injury involves a direct blow to or compression of the neck, basilar skull fracture, cervical hyperextension and rotation, or blunt bilateral perioral fractures. Table 21.3 lists screening criteria for blunt cerebrovascular injury in asymptomatic trauma patients.^{27,30}

The mortality rate remains high with blunt carotid injury, ranging from 20% to 40%, with permanent neurologic impairment in 25% to 80% of survivors.^{41,50–52} There is a reasonably good neurologic outcome, better than 55%, for an uncomplicated arterial dissection and a uniformly poor outcome, with

close to 100% mortality, for complete arterial disruption or bilateral arterial occlusion.^{41,50,51} Treatment is highly variable and the efficacy has not been proven in a prospective study.^{50,51,53} Therapy depends on the type and location of the vascular lesion, concomitant injuries, availability of the interventional techniques, and preference of the treating surgeon. Arterial dissections can be best managed by systemic anticoagulation.⁵¹ For patients with contraindication to full anticoagulation, aspirin and antiplatelet therapy have been suggested.⁵⁰ Anticoagulation is to prevent propagation, embolization, and thrombosis. Stenting and primary surgical therapy, in anatomically favorable locations, have also been used in the management of arterial dissection in small studies.^{41,50,51,54} If it is anatomically feasible, pseudoaneurysms are resected. Larger inaccessible pseudoaneurysms are a difficult management challenge; the treatment includes anticoagulation, balloon occlusion, stenting, ligation, or extracranial-intracranial bypass.^{53,55,56} Patients with carotid-cavernous fistulas have been treated with balloon occlusion with variable results.^{41,51} The outcome of an arterial injury with complete vascular thrombosis depends more on the neurologic status than on any treatment regimen. Nonsurgical management seems appropriate for most of these patients.⁵² The rare and fortunate patient with complete carotid thrombosis without neurologic deficits can best be treated with anticoagulation to prevent further or contralateral damage.

Patients with penetrating carotid artery injury most commonly present with exsanguinating hemorrhage. The principles of operative repair of vascular structures in the neck are the same as those for other major vessels. What makes neck vascular trauma unique is the intolerance of the perfused end organ (brain) to even short periods of ischemia. The indication for repair versus ligation of a carotid injury in part depends on the neurologic presentation. Patients without a neurologic deficit should have restoration of vascular continuity, with a good neurologic outcome anticipated. Patients with all grades of neurologic deficits short of coma should also have primary vascular repair.⁵⁷ Although the experience with revascularization of patients suffering acute stroke from arteriosclerotic occlusive disease suggests that hemorrhagic infarction and death can result from revascularization, several reviews of acute revascularization in the trauma patient note that the combined morbidity and mortality rate is significantly lower in patients undergoing primary repair (15%) compared with those treated with arterial ligation (50%).^{58–60} In comatose patients, neither repair nor ligation appears to influence what is a uniformly poor prognosis. Ligation of the carotid artery is indicated in the comatose patient with no prograde flow, in the presence of uncontrollable hemorrhage, or if technical reasons prohibit repair. There currently is little experience or evidence to favor extracranial-intracranial bypass in the patient requiring carotid artery ligation for trauma, although it has been used selectively in patients requiring selective carotid occlusion.^{61,62}

Vertebral Artery

Traumatic injury to the vertebral artery, once only rarely diagnosed, is now more commonly identified because of the liberal application of neck angiography after both penetrating and blunt neck injuries. Blunt vertebral artery injuries occur more commonly than blunt carotid injuries, probably because of the close association of bony and ligamentous structures. Mechanisms reported to cause vertebral artery injury are remarkably diverse, including hyperextension and rotation, direct blows, chiropractic manipulation, yoga exercises, volleyball, and even “head banging” to heavy metal rock music.^{63,64} Unilateral vertebral artery occlusion seldom results in a neurologic deficit, despite a 15% incidence of congenital unilateral hypoplastic vertebral arteries.⁶⁵ Treatment of blunt vertebral artery injury with thrombosis usually is nonoperative: systemic anticoagulation (if possible) is recommended to avoid further propagation

TABLE 21.3 **DIAGNOSIS**

SCREENING CRITERIA FOR SUSPECTED BLUNT CEREBROVASCULAR INJURY IN ASYMPTOMATIC PATIENTS

- Cervical spine fracture in proximity to internal carotid or vertebral artery
- Skull base fracture extending into the carotid canal
- Le Fort II or III facial fracture
- Extensive soft tissue neck injury such as seat belt injury or hanging
- Diffuse axonal injury
- Mechanism associated with severe cervical hyperextension or hyperflexion
- Significant cervical soft tissue injury

FIGURE 21.5. Normal anatomy of the vertebral artery, showing its division into four parts.

of existing thrombus. More often with penetrating wounds, acute hemorrhage, pseudoaneurysm, and formation of an arteriovenous fistula are reasons for surgically addressing a known vertebral artery injury. Operative exposure and exploration can be difficult. The extraosseous first portion of the vertebral artery can be exposed by a supraclavicular incision with transection of the sternal head of the sternocleidomastoid muscle (Fig. 21.5). More distal exposure (second or third portion) is best obtained by an anterior approach.^{66,67} An incision is made along the anterior border of the sternocleidomastoid muscle, and the carotid sheath is identified and retracted either anterosuperiorly or posteroinferiorly to expose the prevertebral space (Fig. 21.6). Hemoclips are blindly applied where the vertebral artery is free of the osseous vertebral canal between the transverse processes, behind the longus cervicis (colli) muscle. High ligation of the vertebral artery at the C1-2 level (fourth portion) is a satisfactory method of obtaining distal control without unroofing the bony canal of the vertebral artery.^{1,65} Percutaneous embolization both distal and proximal to the site of arterial injury simplifies the management, but it requires a skilled and experienced interventional angiographer to cross the site of injury without causing further, uncorrectable damage. Contralateral vertebral angiography is recommended to accurately determine the extent of injury or the adequacy of embolization.

Trachea and Larynx

Blunt laryngeal trauma typically results from an anterior impact force (e.g., dashboard, steering wheel) that drives the larynx posteriorly against the rigid cervical spine. The impact can produce a simple or comminuted fracture of laryngeal cartilage, disruption of the mucosa of the endolarynx, or perforation and tears of the hypopharynx. Figure 21.7 depicts the critical laryngeal anatomy and the most common blunt injury pattern. These injuries are frequently occult and are often initially overlooked as attention is directed to injuries of the head, face, and thorax. Delayed recognition of blunt laryngeal trauma is the single greatest contributor to mortality, followed by aspiration of blood, missed esophageal injury, and over-

looked concomitant intra-abdominal injury. Subtle clinical signs and symptoms of laryngeal injury cannot be ignored. One report identifies hoarseness as the most common symptom, followed by shortness of breath, inability to tolerate the supine position, pain, dysphagia, and aphonia. Tenderness was identified as the most common clinical sign, followed by subcutaneous emphysema, neck contusion, tracheal deviation, and hemoptysis.⁶⁸ Liberal use of neck CT and fiberoptic endoscopy aids in the diagnosis.⁶⁹

Unlike blunt laryngeal trauma, penetrating injuries to the trachea and larynx are usually readily apparent and dramatic in their clinical presentation. Subcutaneous emphysema (occasionally massive), pain, hoarseness, and respiratory distress are hallmarks of tracheal injury. However, rapid endotracheal intubation by field paramedics can mask a high tracheal injury. Concomitant esophageal, vascular, and thoracic injuries are frequent. A 20-year review of 106 tracheobronchial injuries documented a 22% incidence of concomitant esophageal injuries, a 16% incidence of major vessel injury, and a 40% incidence of hemopneumothorax.⁷⁰

As with any trauma victim, the first treatment priority for those with laryngotracheal injuries is to secure an adequate airway. With a laryngeal injury, this usually straightforward task can be extremely challenging. If an emergency airway is required, direct endotracheal intubation can be attempted initially if the laryngeal structures are well visualized and the endotracheal tube is passed over a flexible endoscope. However, this risks further damage to the trachea even in the most experienced hands. Equipment and preparation for emergency tracheostomy should always be at hand, and tracheostomy is usually recommended if an emergency airway is required, even though it also carries some risk of further injury.⁷¹ Pulse oximetry monitoring is essential, and care must be taken to prevent episodes of hypoxia while alternative airway access techniques are attempted. Transtracheal needle-jet insufflation can temporize a critical situation and allow a more controlled tracheostomy.

Operative repair is usually not required for patients with simple laryngeal edema, hematomas without mucosal disruption, small lacerations of the endolarynx not involving the anterior commissure or the free margin of the vocal fold, and

FIGURE 21.6. Operative approach to the vertebral artery. A: Carotid artery and sheath retracted anteriorly. B: Carotid artery and sheath retracted posteriorly.

FIGURE 21.7. Frontal view (A) and three-quarters view (B) of the larynx.

small lacerations of the supraglottic larynx that do not disrupt the integrity of this site.⁷¹ Indications for primary open repair of the larynx include virtually all penetrating tracheal or laryngeal wounds, vocal cord disruption, mucosal tears with exposed cartilage, thyrohyoid separation, thyroid or cricoid cartilage fractures, and hypopharyngeal perforations. The basic tenets of operative care are débridement of devitalized cartilage, reduction of cartilaginous fractures, mucosal coverage of exposed cartilage, and closure of tracheal defects. Tracheostomy is not always required, but it is useful if extensive edema or prolonged airway control is anticipated. Controversial areas in the surgical care of laryngotracheal trauma patients include the timing of operation, the role of laryngeal stints, the use of steroids, indications for skin grafting, and the techniques of operative exposure of the larynx.⁷²

Pharynx and Esophagus

Esophageal injuries occur in only 5% of patients with penetrating neck wounds. Esophageal perforation from external blunt trauma is rare and accounts for less than 10% of all esophageal perforations.^{73,74} Most blunt injuries are caused by a direct blow to the neck with a hard object, such as a steering wheel in high-speed motor vehicle crashes, but it can occur from minor trauma. Esophageal injury is an uncommon cause of pneumomediastinum. The diagnosis of an esophageal injury can be difficult and requires a high index of suspicion. The clinical signs of esophageal injury, such as hematemesis, odynophagia, neck pain, crepitus, and air in the soft tissues on chest and neck radiographs, are often absent or obscured by concomitant laryngotracheal injury.⁷⁵ In one study, the blunt cervicothoracic esophageal injury had a 56% incidence of associated tracheolaryngeal injury.⁷⁴ In a review of 77 patients with penetrating esophageal injuries, 45 had cervical esophageal wounds.⁷⁶ Overall, physical findings were diagnostic in only 26% of patients. Furthermore, the morbidity of a missed esophageal injury is catastrophic. One review of penetrating neck wounds contained 109 cases of esophageal injuries; the mortality rate was 2% if operation was immediately performed but increased to 44% if operation was delayed because of an initially missed injury and to 100% if no operation was performed.³ This information is widely used as support for a mandatory neck exploration policy. Other authors, however, have documented a small but significant incidence of missed esophageal injury even after neck exploration. In one report, cervical esophageal injury was initially missed at neck exploration in three patients, and all three died.⁷⁶ As a result, an aggressive effort at excluding esophageal injury is warranted, and some authors recommend routine esophagography or esophagoscopy, or both, to aid in the diagnosis of isolated esophageal injuries. The sensitivity of esophagography in detecting esophageal injury varies from approximately 50% to 90%, and the sensitivity of endoscopy varies from 29% to 100%.¹⁸ These modalities should be considered complementary; when combined, they have an accuracy of almost 100%.²⁵ The choice of rigid or flexible esophagoscopy is controversial and probably reflects individual preferences.

Careful evaluation of the entire tract of the offending penetrating agent or region of blunt hematoma is required to document esophageal integrity. This can be technically challenging and time consuming, but it is a crucial component of the neck exploration. Concomitant intraoperative endoscopy, esophageal air insufflation, or even vital dye instillation can be helpful in excluding injury. Because almost all reported deaths from cervical esophageal injuries are the result of a delayed or missed diagnosis, a particularly high level of suspicion is warranted. The key to successful management of cervical esophageal and pharyngeal injury is early adequate drainage.⁷⁷ All such wounds should be drained to avoid deep neck infection or development of a salivary fistula, which occurs in 9%

to 18% of these patients.^{75,78} Esophagography before drain removal is also recommended, because about half of postrepair fistulas are initially clinically silent. The injured esophagus should be meticulously débrided and repaired primarily, in two layers, with absorbable and nonabsorbable sutures. Single-layer closure also may be adequate.^{75,78} A sternocleidomastoid or strap muscle should always be placed between the trachea and esophagus in a combined repair. If primary closure is not realistic or safe, due to an extensive loss of tissue, as with a shotgun blast, it may be necessary to perform a cutaneous esophagostomy for feeding purposes and a cutaneous pharyngostomy for salivary drainage. A secondary reconstructive procedure is then required after the initial healing is complete. Recently, there have been reports of nonoperative management of small injuries confined to the upper hypopharynx, above the arytenoid cartilage, if there are no other associated injuries.⁷⁷ The treatment includes close observation, intravenous antibiotics, upright positioning, and restricted oral intake. Most surgeons advocate primary repair of all esophageal injuries, if it can be accomplished early. Delays of longer than 12 hours significantly increase the risk of repair dehiscence, wound abscess, and death. Neck esophageal injuries diagnosed more than 24 to 48 hours after injury are best managed initially by diversion and drainage.

Nerves

The preoperative determination of level of consciousness and lateralizing gross motor or sensory deficits is required in all patients; a more detailed neurologic examination of the brachial plexus, deep cervical plexus, phrenic nerve, and cranial nerves should be performed in all but the most unstable patients. A hypoglossal or spinal accessory nerve injury is particularly easy to miss unless a preoperative neurologic examination is performed. The vagus nerve can be evaluated by examination of the vocal cords. Primary débridement and repair of all severed or lacerated "named" nerves is preferred, with the use of fine interrupted nonabsorbable sutures on the perineurium. Repair of a *single* recurrent nerve injury is controversial. An avulsed recurrent laryngeal nerve (blunt laryngotracheal disruption) should be implanted into the posterior cricoarytenoid muscle.⁷⁹ If a motor nerve deficit is apparent, an expendable sensory nerve such as the great auricular can be interposed as a nerve graft to allow anastomosis without tension. If the patient's condition precludes primary repair, the nerve ends should be marked with silver clips or nonabsorbable colored sutures. Secondary repair several weeks after injury is advised.

CHAPTER 22 ■ CHEST TRAUMA

THOMAS K. VARGHESE Jr.

KEY POINTS

- 1 Thoracic injuries are a significant source of morbidity and mortality.
- 2 Injuries identified during the primary survey should be corrected as soon as they are identified.
- 3 Immediate life-threatening injuries identified during the secondary survey are not obvious on physical examination. A high degree of suspicion is needed along with appropriate use of diagnostic studies.
- 4 Several manifestations of thoracic trauma are indicative of a greater risk of associated injuries. Subcutaneous emphysema is associated with airway or lung injury. Injuries to the upper ribs (1 through 3), scapula, and sternum are associated with significant mechanisms of injury.
- 5 In situations where a significant mechanism of force has occurred, underlying head, spine, and thoracic injuries should be suspected.

- 1 Thoracic injuries account for 25% of immediate trauma-related deaths, second only to head and spinal cord injuries.¹ For those who survive the initial trauma, an additional 25% will die within the first year from complications.² Initial assessment and treatment of patients with thoracic trauma consists of the primary survey and intervention, resuscitation of vital functions, detailed secondary survey, and definitive care.

- 2 Major thoracic injuries can be grouped together as the “fatal 14” (Table 22.1). The lethal six (airway obstruction, tension pneumothorax, open pneumothorax, flail chest with pulmonary contusion, massive hemothorax, and cardiac tamponade) are immediate life-threatening injuries that should be corrected as they are being identified during the primary survey.
- 3 The hidden eight (simple pneumothorax, hemothorax, pulmonary contusion, tracheobronchial tree injury, blunt cardiac injury, traumatic aortic disruption, traumatic diaphragmatic tear, and esophageal rupture) are potentially life-threatening injuries that should be detected during the secondary survey with subsequent definitive treatment.

TREATMENT OF INJURIES DURING THE PRIMARY SURVEY

Airway Assessment

The first priority in treating trauma patients is airway management. Trauma personnel rarely see acute airway injuries presenting to the emergency department (ED), which is likely the result of the high fatality rate at the scene secondary to aspiration of blood, secretions, and debris causing an acute airway obstruction. Acute management of the airway should follow the guidelines proposed and updated regularly by the American College of Surgeons Committee on Trauma for Advanced Trauma Life Support (ATLS). The cornerstones of airway management are adequate oxygenation, ventilation, and protection from aspiration. Airway patency and air exchange should be assessed by listening for air movement at the patient's nose, mouth, and lung fields; inspecting the oropharynx for airway obstruction; and observing for intercostal and supraclavicular muscle retractions. Orotracheal intubation with appropriate cervical spine immobilization and direct laryngoscopy is the most common important first step in

establishing a secure airway. However, extreme caution is needed in the face of significant maxillofacial trauma and suspicion of laryngeal trauma. The flexible bronchoscope can serve as an important aid in the diagnosis and management of the injured airway. However, this may take some time to perform even in the most experienced hands. The status of the larynx may be assessed with a bronchoscope and a decision can be made to continue with orotracheal tube insertion over the bronchoscope versus proceeding with placement of a surgical airway.

A cricothyrotomy may play a lifesaving role when orotracheal intubation is not possible and should not be delayed by excessive attempts at orotracheal intubation. It is contraindicated in the presence of a rare laryngeal or cricoid cartilage injury. It may also be difficult to perform in the face of an expanding neck hematoma or significant subcutaneous emphysema. And, while a tracheostomy in the acute setting is difficult to perform, it is indicated in the face of severe laryngeal trauma, as well as in the setting of a disrupted cervical trachea, where the endotracheal tube can be placed directly through the injured area (Fig. 22.1).

Posterior dislocation of the clavicular head also can cause upper airway obstruction after injury to the upper chest. The injury should be suspected when there is presence of a palpable defect in the sternoclavicular joint associated with stridor or change in voice quality. Closed reduction of the dislocation can be achieved either by extension of the shoulders or by direct grasping of the clavicle with a towel clip to manually reduce the dislocation.

BREATHING

Complete exposure of the patient's chest and neck allows for assessment of breathing and the neck veins. Signs of chest injury or hypoxia include increased respiratory rate or change in breathing pattern.

Tension Pneumothorax

- 4 Tension pneumothorax develops secondary to a bronchopleural fistula (BPF) acting as a one-way valve, allowing for air entry into the pleural space from a defect in the lung

TABLE 22.1**CLASSIFICATION OF MAJOR THORACIC INJURIES ("FATAL 14")**

- A. Injuries identified during the primary survey ("lethal six")
- Airway obstruction
 - Tension pneumothorax
 - Open pneumothorax
 - Flail chest with pulmonary contusion
 - Massive hemothorax
 - Cardiac tamponade
- B. Injuries identified during the secondary survey ("hidden eight")
- Simple pneumothorax
 - Hemothorax
 - Pulmonary contusion
 - Tracheobronchial tree injury
 - Blunt cardiac injury
 - Traumatic aortic disruption
 - Traumatic diaphragmatic tear
 - Esophageal rupture

parenchyma or airway (Fig. 22.2). The one-way valve effect can also occur through a defect in the chest wall. As a result of the sudden increase of air in the pleural space, the ipsilateral lung collapses, and the mediastinum shifts to the opposite side. This interferes with expansion of the contralateral lung and causes accompanying compromise of venous return to the heart. The associated hypotension is due to impaired filling pressures of the myocardium.

The most common cause of tension pneumothorax is positive-pressure mechanical ventilation in patients with visceral pleural injury. It can also occur as a complication of a simple pneumothorax after penetrating or blunt chest trauma when the lung parenchyma fails to seal. Traumatic defects in the

chest wall may also cause a tension pneumothorax if the defect itself acts as a one-way flap valve or if the defect is incorrectly covered with an occlusive dressing without chest tube placement.

A tension pneumothorax is a clinical diagnosis reflecting air under pressure in the pleural space. In the setting of clinical suspicion and physical signs, treatment should be immediate and not be delayed for a chest radiograph. Signs and symptoms of tension pneumothorax include chest pain, respiratory distress, tachycardia, hypotension, tracheal deviation, unilateral absence of breath sounds, and neck vein distention. As these signs are similar to cardiac tamponade, differentiation should be made by hyperresonance on percussion and absence of breath sounds on the affected side. Both tension pneumothorax and massive hemothorax are associated with decreased breath sounds on auscultation. Differentiation on physical examination is made by percussion; hyperresonance confirms a pneumothorax, whereas dullness is present with a massive hemothorax. The possibility of an occult acute tension pneumothorax should also be entertained in the setting of a critically ill patient being mechanically ventilated who has a high peak airway pressure (>30 cm H_2O), requires high positive end-expiratory pressure (PEEP; >15 cm), has a history of thoracic trauma or chronic obstructive pulmonary disease, or decompensates immediately after an intervention (e.g., central line placement, bronchoscopy, deep endotracheal suctioning). Immediate treatment includes emergency needle decompression and aspiration, followed by chest tube placement. A standard large-bore intravenous catheter is inserted into the second intercostal space in the midclavicular line of the affected hemithorax. This maneuver converts the injury to a simple pneumothorax. Definitive therapy soon follows in the form of insertion of a chest tube, usually in the fifth intercostal space just anterior to the midaxillary line.

Open Pneumothorax

Chest wall defects that are significantly large can remain open and result in an open pneumothorax. Such wounds usually

FIGURE 22.1. A 27-year-old patient with history of a 200-lb bag of fertilizer falling onto the back of the neck with subsequent hyperextension and disruption of the cervical trachea. **A:** Patient's airway is stabilized with an endotracheal tube placed into the distal trachea. **B:** Primary repair of the cervical trachea is performed with interrupted 4-0 Vicryl sutures.

FIGURE 22.2. A: Simple pneumothorax: air collects between the lung and chest wall. B: Tension pneumothorax: air collects between the lung and chest wall, with associated mediastinal shift. This leads to compression of venous structures and subsequent decreased venous return to the heart.

occur from high-velocity missiles or shotguns fired at close range. The large opening leads to immediate equilibration between the atmospheric pressure and intrathoracic pressure. If the opening of the chest wall is at least two-thirds the circumference of the trachea, air passes preferentially through the chest wound with each breath rather than down the tracheo-bronchial tree. Ventilation is thus compromised leading to significant hypoxia and hypercarbia. The airway is controlled with early intubation and mechanical ventilation. The defect is promptly closed with a sterile occlusive dressing, large enough to overlap the wound's edges and taped securely only on three sides in order to provide a flutter-type valve effect (Fig. 22.3). As the patient breathes in, the dressing occludes the wound,

preventing air entry through the chest wall. When the patient exhales, the open end of the dressing allows air to escape from the pleural space. A chest tube is placed remotely from the wound.

The next priority is to address any underlying intrathoracic injuries. If definitive surgical intervention is needed, an attempt is made to make the thoracotomy in such a fashion to preserve blood supply and muscle mass of the chest wall adjacent to the defect. After repair of intrathoracic injuries and débridement of devitalized tissue, the next step is to plan the definitive closure of the wound. In the interim, aggressive wound débridement, drainage of pneumothorax and/or hemothorax, and simple packing are appropriate.³ A dreaded complication of chest

FIGURE 22.3. Occlusive dressing for open pneumothorax: an open pneumothorax occurs when there is a pneumothorax associated with a chest wall defect such that the pneumothorax communicates with the exterior. Treatment entails placing an occlusive dressing as well as an intercostal drain (chest tube). The occlusive dressing is airtight on three sides. A: Inspiration: the occlusive dressing prevents air entry into the chest. B: Expiration: air escapes from the wound and exits at the inferior aspect of the dressing.

wounds is necrotizing infection.⁴ These infectious complications need wide local débridement and reconstruction. Most chest wall defects can be closed with viable autogenous tissue, usually through rotation of local flaps of the pectoral muscle, latissimus dorsi, or rectus abdominus. Collaboration between trauma surgeons, plastic surgeons, and thoracic surgeons is often helpful in these complex cases. Extensive injuries may dictate the need for mesh reconstruction with either Gore-Tex or methyl methacrylate.

Flail Chest with Pulmonary Contusion

Flail chest requires complete dissociation of a portion of the chest wall by segmental fractures of two or more adjacent ribs (Fig. 22.4). It may also arise from either disruption of the ribs from the sternum at the costochondral cartilage or a fracture in the ribs (sternal flail; Fig. 22.5). In addition to the disarray in chest wall mechanics, the force needed to cause the injury often leads to significant underlying intrathoracic, primarily

pulmonary parenchyma, injury. Although chest wall instability leads to paradoxical motion of the chest wall during inspiration and expiration, the major difficulty in flail chest is the injury to the lung (pulmonary contusion). Additional restriction in chest wall movement from the associated pain further exacerbates hypoxia.

There has been intense debate about the role of surgical intervention for flail chest. In the pre-ventilator era, intervention centered on external fixation techniques such as external strapping, the placement of sandbags, or even external fixation combined with traction.⁵ The significant rate of complications, prolonged bed rest needed for fracture union, and high failure rates led to early ventures in internal fixation. However, the use of positive-pressure mechanical ventilation (internal splinting) led to the observation of adequate stabilization in most patients, and hence the enthusiasm for surgical intervention waned. Only select patients who had persistent flail despite mechanical ventilation had a variety of attempted rib fracture repairs done with plates, wires, and intramedullary techniques. Recently, two randomized trials suggested that patients may

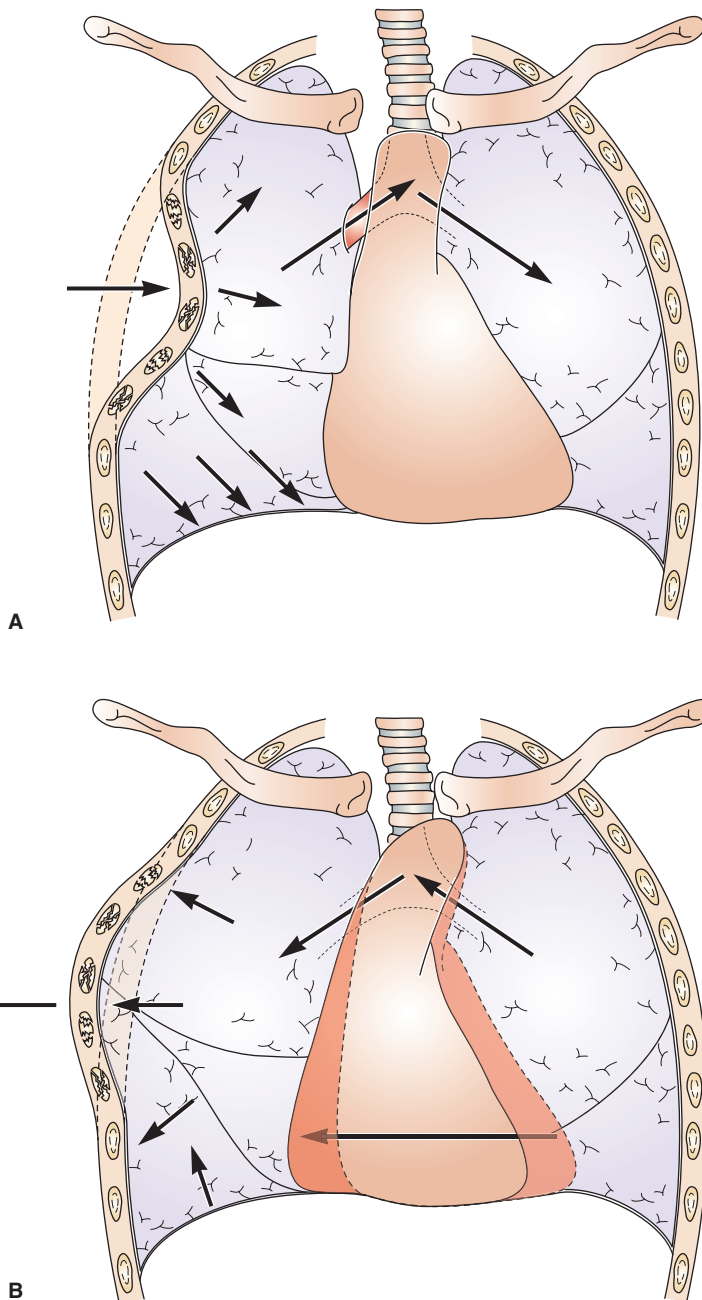

FIGURE 22.4. Pathophysiology of flail chest. **A:** Inspiratory phase: chest wall collapses inward, causing air to move out of the bronchus of the involved lung into the trachea and bronchus of the uninvolved lung, causing a shift of mediastinum to the uninvolved side. **B:** Expiratory phase: chest wall balloons outward so that air is expelled from the lung on the uninvolved side and enters the lung on the involved side with an associated shift of mediastinum to the involved side.

FIGURE 22.5. Sternal flail.

benefit from early operative repair. In one trial, 37 flail chest patients who required mechanical ventilation were randomized to surgical stabilization or nonoperative management.⁶ The surgical group had fewer days on the ventilator, a shorter intensive care unit (ICU) stay, a lower incidence of pneumonia, and a better pulmonary function at 1 month, as well as a higher return to work percentage at 6 months, compared to the nonoperative group. A second trial randomized 40 patients in similar fashion.⁷ The surgical group again had fewer days on the ventilator, decreased ICU and inpatient stays, and less pneumonia than the nonoperative cohort. There was a reported higher forced vital capacity and total lung capacity at 2 months, as well as decreased incidence of visual chest wall deformity or persistent flail. Other nonrandomized, case-control studies have supported these findings in those patients without major pulmonary contusions.^{8–11} However, currently most trauma centers maintain the belief that the vast majority of patients with flail chest are satisfactorily managed without surgical intervention.

Initial treatment of flail chest entails oxygenation, judicious fluid administration, and providing adequate analgesia to improve ventilation. Prevention of hypoxia is paramount in these patients, and thus a period of intubation and ventilation may be necessary until all injuries are delineated. Once the ventilation status is stabilized, the remainder of the primary and secondary survey are completed, and the patient is admitted to the ICU. Surgical intervention may be considered in those patients who remain ventilator dependent despite apparent resolution of underlying pulmonary contusions. However, the definitive role for surgical intervention may not be determined until a randomized multicenter clinical trial addresses this issue.

CIRCULATION

After acute life-threatening airway and breathing issues are addressed during the primary survey, the patient is assessed for hypovolemia. The pulse is noted for its quality, rate, and regu-

larity. Neck veins should be noted for distention. Cardiac contusions can lead to arrhythmias, which can be exacerbated with hypoxia and acidosis. Major thoracic injuries that affect circulation should be addressed during the primary survey, such as massive hemothorax and cardiac tamponade.

Massive Hemothorax

Massive hemothorax results from the collection of more than 1,500 mL of blood (30% to 40% of total blood volume) rapidly in the chest. This occurs most often with a penetrating wound with a systemic or hilar vessel injury, though it can also occur with blunt trauma. Penetrating anterior chest wounds medial to the nipple line and posterior wounds medial to the scapula should alert to the likelihood of an injury to the great vessels, hilar structures, and the heart. A massive hemothorax is suspected when shock accompanies absence of breath sounds and dullness to percussion on one side of the chest. Blood loss is complicated by hypoxia, as the significant rapid accumulation of blood in the chest compromises respiratory efforts by mechanically compressing the lung and preventing adequate ventilation. Initial management includes simultaneous restoration of blood volume along with decompression of the chest cavity with a chest tube to evacuate the blood. If greater than 1,000 mL of blood is drained by the initial chest tube, an additional tube should be placed to ensure better evacuation and hemostasis and to avoid potential problems from clot formation and occlusion of the initial tube. Traditional criteria for taking the patient to the operating room (OR) for a thoracotomy are initial output of more than 1,500 mL of blood or continuing blood loss of 200 mL/h for 2 to 4 hours. Need for blood transfusions to maintain blood pressure represents hemorrhagic shock and is an indication for thoracotomy. In the OR, evacuated blood can ideally be collected in a device capable of autotransfusion.

Cardiac Tamponade

Cardiac tamponade is more often seen in penetrating injuries than blunt. Filling of the pericardium with blood can occur with injuries to the heart, great vessels, or pericardial vessels. Regardless of the mechanism, the collection of blood in the pericardium can result in tamponade physiology. Only a relatively small amount of blood in the relatively fixed fibrous sac (i.e., the pericardium) is needed to restrict cardiac activity and impair cardiac filling. Rising intrapericardial pressure causes hemodynamic instability and decreased cardiac perfusion, classically described in three phases.¹² In the first phase, rising pericardial pressure restricts ventricular diastolic filling and reduces subendocardial blood flow.¹³ In this phase cardiac output is maintained by compensatory tachycardia, increased systemic vascular resistance, and elevated ventricular filling pressure. In the second phase, rising pericardial pressure further compromises diastolic filling, stroke volume, and coronary perfusion, resulting in diminished cardiac output. Initial signs of shock such as anxiety, diaphoresis, and pallor become evident in this phase. In the third phase, compensatory mechanisms fail as the intrapericardial pressure approaches the ventricular filling pressure. Cardiac arrest results as profound coronary hypoperfusion occurs.

Signs of cardiac tamponade may be difficult to detect. Beck's triad of muffled heart sounds, jugular venous distention, and pulsus paradoxus is present in only 15% of patients who are later judged to have tamponade.¹⁴ Differences in blood pressure greater than 10 mm Hg suggest accentuation of the physiologic drop in pressure associated with inspiration. Pulsus paradoxus can be difficult to detect in a noisy emergency room with a tachypneic patient. However, chest radiography can occasionally but unreliably demonstrate a widened

cardiac shadow. Central venous pressure (CVP) reflecting elevated pressures can lead to the diagnosis, but may be absent due to hypovolemia. Elevated CVP and pulseless electrical activity (PEA) are nonspecific signs. Prompt diagnosis and evacuation of pericardial blood are indicated for patients who do not respond to the usual measures of resuscitation for hemorrhagic shock and have the potential for cardiac tamponade. Methods that are rapid and accurate in assessing cardiac injuries include focused sonogram in trauma (FAST) and echocardiography.¹⁵ The presence of a pericardial effusion is diagnostic. However, its absence does not necessarily rule out injury.¹⁶ Specifically, echocardiography cannot reliably rule out cardiac injury in the setting of an associated left pleural effusion. This occurs due to the effusion obscuring the pericardium or the effusion occurring as a result of a pericardial tear and escape of blood from the pericardium into the pleural space. In this circumstance, the pericardial sac may be empty.

In the first two phases of cardiac tamponade, patients may be aggressively managed with definitive airway control and volume resuscitation, and may be temporized with an attempted pericardiocentesis. However, definitive intervention requires taking the patient to the OR for a pericardial window or immediate median sternotomy. A pericardial window is typically performed through the subxiphoid approach, although there is a role for thoracoscopy in the stable patient with an associated hemothorax or if the abdominal route is to be avoided in the case of intra-abdominal contamination.¹⁷ When the diagnosis is highly likely due to pattern or injury, hemodynamic responses, and/or ultrasound (FAST) results, a primary median sternotomy may be indicated prior to further physiologic deterioration for both definitive diagnosis and treatment. In the third phase of tamponade, patients have profound hypotension and should undergo ED thoracotomy (EDT) for evacuation of pericardial blood. Following the release of tamponade, the source of bleeding is directly controlled.

Emergency Department Thoracotomy. With the advent of regionalized trauma systems, the number of patients who, rather than dying in the field, arrive in extremis has increased. Closed heart massage for cardiac arrest or PEA is ineffective in patients with hypovolemia. Patients with penetrating thoracic injuries who arrive pulseless but with signs of life (reactive pupils, spontaneous movements, or organized electrocardiographic [ECG] activity) are candidates for immediate resuscitative thoracotomy. The other set of patients who may benefit from EDT are those patients with either blunt or penetrating thoracic injuries who lose their vitals in the trauma bay. EDT refers to the use of a resuscitative thoracotomy in the ED for those patients in extremis. A left anterolateral thoracotomy incision is preferred for EDT (Fig. 22.6). This enables the procedure to be performed in the supine position and allows for ongoing cardiac massage, and extension into the right hemithorax can be achieved with a clamshell thoracotomy and subsequent exposure of both pleural spaces, as well as mediastinal structures. EDT is performed to correct the cause of cardiovascular collapse from mechanical sources or extreme hypovolemia. The objectives of EDT are to (a) release pericardial tamponade, (b) control cardiac hemorrhage, (c) control intrathoracic bleeding, (d) evacuate massive air embolism, (e) perform open cardiac massage, and (f) temporarily occlude the descending thoracic aorta.¹⁸ The highest survival rate following EDT is in patients with penetrating cardiac wounds, especially with pericardial tamponade.¹⁹ The rationale for temporary thoracic aortic clamping with massive hemorrhage is twofold. First, aortic clamping redistributes the patient's limited blood volume to the myocardium and brain. Second, there may be decreased ongoing subdiaphragmatic blood loss in those patients with significant intra-abdominal injuries. However, once the patient's blood volume has been restored after repair of the injury, the aortic cross-clamp should be removed expeditiously. Persistent clamping in this situation can result in

FIGURE 22.6. Left anterolateral thoracotomy incision.

increased myocardial demand, increasing acidosis from malperfusion, and risk of paraplegia.

In a patient with a penetrating chest injury who develops profound hypotension and cardiac arrest following endotracheal intubation and positive-pressure ventilation, a bronchovenous air embolism should be suspected. The traumatic alveolar-venous communication leads to migration of the air embolism to the coronary circulation, with resultant myocardial ischemia and shock. The associated low pulmonary venous pressure from intrathoracic blood loss and high bronchoalveolar pressure from positive-pressure ventilation increase the gradient for air transfer across the bronchovenous channels.²⁰ Immediate thoracotomy with pulmonary hilar cross-clamping prevents further pulmonary venous embolism. The pericardium is opened, and with the patient in Trendelenburg position, air trapped in the ventricles is removed by aspiration. Cardiac massage may also dissolve air present in the coronary arteries. Aspiration of the aortic root is also done to remove any additional accumulated air.

Analysis of the literature on EDT indicates that the success rates approach 35% in the patient arriving in shock with penetrating cardiac wounds and 15% for all penetrating wounds.¹⁸ In contrast, the results of EDT are poor in the setting of blunt trauma, with a survival of only 1% to 2%. Patients undergoing cardiopulmonary resuscitation (CPR) prior to arrival in the ED should be stratified based on the type of injury and transport time to assess the potential utility of EDT.

TREATMENT OF INJURIES DURING THE SECONDARY SURVEY

The secondary survey includes detailed physical examination, a chest radiograph (ideally upright, injuries permitting), arterial blood gas measurements, pulse oximetry, and ECG monitoring. The chest radiograph is examined for adequate lung expansion, presence of fluid, widening of the mediastinum, mediastinal shift, and loss of anatomic detail. Multiple rib fractures and fractures of the first and second ribs are indicative of a severe force delivered to the chest. Unlike the previously described immediate life-threatening conditions, injuries detected during the secondary survey are not obvious on physical examination. A high degree of suspicion is needed, along with appropriate studies.

SIMPLE PNEUMOTHORAX

A pneumothorax is one of the most common traumatic injuries, with a reported prevalence of 20% in patients arriving alive to trauma centers.²¹ There are three types of pneumothoraces: simple, open, and tension. A simple pneumothorax is a collection of air trapped in the pleural space. The most common cause is air leaking into the pleural space as a result of a parenchymal lung injury. Open pneumothorax occurs when wounds of the chest wall allow air to enter the pleural space from the outside. A tension pneumothorax occurs when air collects in the pleural space under pressures exceeding atmospheric pressure. This pressure collapses the affected lung and is transmitted to the mediastinal structures, leading to a shift of the heart and great vessels away from the side of the pneumothorax.

The etiology of a pneumothorax differs in blunt and penetrating trauma. Pneumothoraces following blunt trauma may occur from (a) a sudden increase in intrathoracic pressure leading to ruptured alveoli and air leak, (b) rib fractures lacerating the lung, (c) deceleration injuries tearing the lung, or (d) blunt forces directly crushing and disrupting alveoli. In penetrating trauma, the etiology is the direct laceration of lung parenchyma.

A definitive diagnosis is made on chest radiography (Fig. 22.7). Associated findings include subcutaneous emphysema, decreased breath sounds, and overlying chest wounds. With the increased use of computed tomography (CT) in the evaluation of the trauma patient, it is apparent that pneumothoraces can be missed on supine anteroposterior (AP) chest radiography. This rate of missed pneumothorax has been estimated to be as high as 20% to 35%. The patient's symptoms and physiologic response to the pneumothorax is significantly more important than the apparent size and should dictate the urgency of treatment.

There is debate regarding the management of patients whose pneumothorax is visible only on CT and not on a chest radiography. The reported incidence of these occult pneumothoraces is between 2% and 8% of all blunt trauma patients.^{22,23} In one retrospective study, the size of the occult pneumothorax was correlated with the need for a chest tube, and recommendation was made for chest tube placement in all pneumothoraces greater than 5×80 mm in size.²⁴ These authors also

suggested a chest tube be placed for those with two or more rib fractures. In another prospective study,²⁵ 8 out of 15 patients on positive-pressure ventilation required chest tubes, with three of these patients having developed tension pneumothoraces. The authors thus recommended chest tubes to be placed for all patients with occult pneumothoraces and requiring positive-pressure ventilation. In contrast, Brasel et al. in a prospective study of 44 patients found that neither size nor positive-pressure ventilation correlated with the development of clinically significant pneumothorax that needed a chest tube.²⁶ Thus, the treatment of an occult pneumothorax should be done in the context of the whole patient. In the stable patient an occult pneumothorax may be observed, but in those with multiple injuries, it would be wiser to place a chest tube. Serial examinations in those patients observed include repeat chest radiographs at 6 and 24 hours.

Currently, the standard treatment for a traumatic pneumothorax found on the screening AP chest radiograph is placement of a chest tube to allow for reexpansion of the lung and apposition of visceral and parietal pleurae. Supplemental oxygen may be tried to enhance reabsorption of the pneumothorax, but it is unlikely that high inspired oxygen tensions (>60%) will provide any more benefit than O₂ given by nasal prongs.²⁷

HEMOTHORAX

Hemothorax is the collection of blood within the pleural space. This can occur as a result of pulmonary parenchymal lacerations, intercostal artery or vein laceration, or disruption of major pulmonary or bronchial vessels. Because parenchymal tears result in low-pressure pulmonary vessel injury, they usually stop bleeding with chest tube intervention and full expansion of the lung. The presence of retained blood in the chest can lead to complications such as empyema and restrictive fibrothorax. Early evacuation of hemothorax is thus ideal. The vast majority of hemothoraces can be drained with chest tube placement alone. Chest tubes fail to completely evacuate a hemothorax in approximately 5% of cases.²⁸ Conditions that can increase the chance of complications in retained fluid collections include prolonged ventilation, pleural disruption, the development of pneumonia, and other distant sites of

FIGURE 22.7. A: Chest radiograph demonstrating simple pneumothorax. B: Resolution of pneumothorax after chest tube placement.

infection. This is in contrast to the stable, nonventilated patient with small effusions (less than one fourth of the hemithorax) following blunt trauma with no obvious pleural disruption, who may be observed without intervention.²⁹

Recognizing the true extent of a hemothorax can be challenging. Plain chest radiographs, especially done with portable equipment, can be misleading and typically underestimate the true extent of the fluid collection. Chest CT is much more accurate in quantification of total amount of blood, as well as assessment for loculations, entrapped lung, and parenchymal damage.³⁰ Moderate effusions in the ventilated patient or effusions in those patients with other risk factors for complications should be drained. However, it may be difficult to drain hemothoraces in patients where recognition occurs more than 24 hours after injury due to clot formation and early loculation. In these patients, chest tube placement may lead to inadequate drainage while increasing the pain, splinting, and risk of pneumonia. One option is the instillation of a thrombolytic agent via the chest tube. Intrapleural streptokinase (250,000 IU) or urokinase (40,000 IU) has been reported to have an efficacy ranging from 65% to 90%.³¹ Although the risk of rebleeding is negligible, disadvantages to their use include associated fever, severe pain, several days for full effect, and ultimate inability to break down some loculations.

Video-assisted thoracoscopic surgery (VATS) is an effective minimally invasive means of definitively addressing significant hemothoraces persisting after failed chest tube drainage or a delayed diagnosis. The VATS approach is well suited for the treatment of hemothorax, breaking down areas of loculation, and completely evacuating gelatinous exudates and clots from the pleural space. Early fibrinous peels can usually be removed from the visceral pleural surface to free any lung entrapment. At the conclusion of the procedure, strategically placed chest tubes lead to full expansion of the lung and resolution of the process. In one prospective study, patients undergoing VATS early after trauma had decreased length of time requiring chest tube drainage, decreased hospital length of stay (2.7 days less), and subsequent decreased hospital cost (\$6,000 less) compared to patients treated with a second chest tube.³² There were no failures or complications, and no patients required conversion to a full thoracotomy with early VATS. In contrast, placement of a second chest tube failed to completely evacuate the retained hemothorax, requiring operative intervention in over 40% of patients.

VATS should be considered carefully to identify patients in whom it may not be feasible. Possible contraindications include (a) compromised pleural cavity due to previous granulomatous infections, empyema, or thoracotomy; (b) inability to tolerate single-lung ventilation secondary to contralateral pulmonary resection, acute or chronic respiratory insufficiency, high levels of required oxygen on mechanical ventilation, or hemodynamic instability; and (c) bleeding diathesis.³³ In these situations, a formal thoracotomy should be considered. Decortication of a mature visceral pleural peel requires an open approach, as do those situations where dense adhesions are anticipated. If a patient presents late (>3 months following the injury), a fibrothorax typically forms. This rare group of patients should initially be managed nonoperatively, if there is no evidence of infection, as there may be remodeling and adaptation at 6 to 9 months. If surgical intervention is needed, there is no added difficulty in performing the procedure at this later date.

PULMONARY CONTUSION AND PARENCHYMAL INJURIES

A pulmonary contusion is a serious injury to the lung parenchyma and is the most common potentially life-threatening chest injury. Most reviews report a mortality of 5% to 30%, and contusion is the direct cause of death in 25% to 50% of

TABLE 22.2

SIGNS OF PULMONARY CONTUSION

- Hypoxemia ($\text{PaO}_2 < 60$ mm Hg) on room air
- Hypercarbia
- Increased work of breathing
- Hemoptysis
- Loss of lung compliance
- Elevated intrapulmonary shunting
- Ventilation/perfusion mismatch

fatalities. Transmission of force (with or without rib fractures) leads to interstitial hemorrhage with resulting alveolar collapse, atelectasis, and consolidation of the uninjured areas of lung.³⁴ As edema forms around the area of initial injury, compliance decreases and work of ventilation increases. Resulting hypoxia occurs due to increased shunting of blood through unventilated lung.³⁵ The hypoxia and respiratory embarrassment typically are maximal within the first 24 to 48 hours and are exacerbated by the extent of injury and the associated need for volume replacement.³⁶ Chest radiographs usually appear normal at the time of initial presentation but then progress to show patchy infiltrates or nonsegmental areas of opacification within the first 4 to 6 hours after injury, usually in areas that underlie rib, clavicle, or sternal fractures. There is a direct correlation between the extent of abnormalities seen on chest radiography and the severity of the injury, and any abnormalities seen on the admission trauma series portend a severe pulmonary contusion. The degree of injury severity can be better assessed by chest CT, where pulmonary contusion appears as an ill-defined area of consolidation. However, routine assessment by CT does not significantly alter therapy or improve outcomes.³⁷

The full assessment of pulmonary contusions is made through the correlation of clinical signs with radiographic findings and laboratory values (Table 22.2).³⁸ Any patient who has suffered a high-impact blunt impact to the chest should be suspected of having a pulmonary contusion. Arterial blood gases demonstrate an arterial hypoxemia on room air and hypercarbia. The degree of clinical lung injury can be assessed using a ratio of partial pressure of arterial oxygen (PaO_2) to the fraction of inspired oxygen (FiO_2)³⁹:

- $\text{PaO}_2/\text{FiO}_2$ ratio less than 300 = acute lung injury
- $\text{PaO}_2/\text{FiO}_2$ ratio less than 200 = acute respiratory distress syndrome

A study by Tyburski et al.⁴⁰ demonstrated that quantifying the extent of pulmonary contusions on chest radiography and serial $\text{PaO}_2/\text{FiO}_2$ ratios in the first 24 hours after injury can aid in predicting the need for ventilatory support and patient outcome. An initial $\text{PaO}_2/\text{FiO}_2$ ratio less than 300 that continues to remain less than 300 at 24 hours after injury was the most significant factor correlating with the need for mechanical ventilation.

Management of pulmonary contusions is supportive initially, with goals of adequate oxygenation and decreased work of breathing. Early measures include supplemental oxygen to prevent hypoxemia, chest expansion through the use of incentive spirometry, Acapella flutter valve therapy to promote deep breathing and coughing, control of pain, and increased activity and mobilization to promote perfusion in all areas of the lung. Fluid volume should be restricted as much as possible, as obligatory capillary leaks lead to worsening pulmonary edema. Control of pain is critical in patients with limited chest excursion as a result of pain from rib fractures, chest wall contusion, and other injuries. Inadequate pain relief can lead to hypoventilation, promotion of atelectasis, and worsening hypoxemia. Epidural analgesia or patient-controlled analgesia using opioids and fentanyl patch should be considered, especially in the setting of rib fractures.³⁵

Adequate oxygenation should be maintained to achieve a PaO_2 of 60 mm Hg and an oxygen saturation of 90%. Early intubation in this patient population is controversial at present. Intubation should be reserved for the classical indications, although the need for intubation and mechanical ventilation can lead to a 44% incidence of pneumonia. There is no role for routine antibiotic prophylaxis in this patient population. Hemodynamic monitoring with a central mixed venous oxygen saturation catheter can help in monitoring severe pulmonary injuries. A decrease in venous oxygen saturation (60% to 70%) is indicative of inadequate oxygenation and perfusion.

It has been estimated that 20% to 30% of patients who undergo thoracotomy following trauma will require some form of lung resection. Most patients who present with penetrating injuries have peripheral injuries that are simple to manage, whereas extensive blast or blunt trauma often results in combinations of diffuse contusion and lung maceration that is extremely difficult to salvage. The most common procedures required are simple suture repair or wedge resection. Tractotomy is used to either define and, in particular, control bleeding to the tracheobronchial tree in deep injuries or to manage peripheral injuries that pass through the parenchyma. Mortality rates as high as 3% to 50% following lobectomy and 70% to 100% following pneumonectomy reflect the severity of lung and overall injury in patients requiring extensive resection. The use of nonanatomic and stapling techniques has been advocated as a method of both damage control and rapid definitive resection with reduced operative time and blood loss and increased parenchymal salvage.⁴¹

TRACHEOBRONCHIAL TREE INJURY

Disruption or injury to a major bronchus or trachea is a rare potentially fatal condition that is often overlooked on initial assessment. It has been reported to occur in 1% to 3% of motor vehicle collisions, and more than 80% die in the field.^{42,43} Those who reach the hospital alive have a high mortality rate from associated injuries. The injury, alone or in combination, is in the distal trachea within 2 cm of the carina in 76% of cases and in the right main stem within 2 cm of the carina in 43%. Approximately 50% of the injuries are circumferential.⁴⁴ In contrast, penetrating injuries involve the cervical trachea in greater than 80% of cases.

A high degree of suspicion is needed to detect these injuries in a timely manner. Clinical signs include subcutaneous emphysema, continuous large air leaks seen in chest tubes, and hemoptysis.⁴⁵ Although a chest radiograph is nonspecific, a pneumothorax, cervical emphysema, or pneumomediastinum may be present. A chest CT scan is more sensitive for detecting pneumomediastinum, and occasionally a “fallen lung sign” may be present, where the lung is seen to fall away from the hilum.⁴⁶ A persistent pneumothorax, despite a well-placed chest tube, and a continuous air leak throughout the entire respiratory cycle are also signs of a possible tracheobronchial disruption.

The first priority is airway control. Orotracheal intubation with appropriate cervical spine precautions and direct laryngoscopy is typically an appropriate first step in securing the airway. Caution should be used in the setting of maxillofacial trauma or suspicion of laryngeal trauma. Flexible bronchoscopy plays a role in the diagnosis and management of the injured airway. It can be used even in the most difficult airway while maintaining cervical spine immobilization. It allows for the accurate placement of distal tubes in the airway that can act as a stent for the disrupted trachea or mainstem bronchi. The status of the larynx can be assessed and a decision made to continue with the tube insertion over the bronchoscope versus aborting intubation and proceeding with a definite surgical airway. Tracheostomy is preferred over a cricothyroidotomy, as the latter can lead to com-

plete airway separation and loss of ability to intubate in this setting. A smooth-end endotracheal tube such as an Armoured wired endotracheal tube of at least 8.0 French should be used. Adequate suctioning and bronchoscopy are possible with the 8.0 size, and the smooth-end reinforced tube reduces the risk of aggravating the airway tear, is easier to place, can be passed across the injury site, and can be manipulated during surgery. On occasion, the distal airway must be intubated through the operative field to allow for adequate exposure.

A patient who deteriorates after intubation, ventilation, and appropriate chest tube placement and subsequently develops a massive air leak should have immediate bronchoscopy. The timing and type of definitive repair depend on the site, extent, and association with other injuries. The proximal two thirds of the trachea is best approached via a low collar incision. This also allows access to the esophagus and cervical vessels in case of associated injury. The collar incision can be extended down into the manubrium with an upper sternal split (“T incision”) for greater exposure of the middle third of the trachea, as well as facilitate control of the proximal innominate artery and vein. If there is any suspicion of injury to a great vessel, the ascending aorta, or the heart, median sternotomy should be employed.⁴³ The distal one third of the trachea and right mainstem bronchus is best approached by a right posterolateral thoracotomy via the fourth or fifth intercostal space. A left posterolateral thoracotomy through the fourth or fifth intercostal space gives one access to the left mainstem bronchus and the proximal left subclavian artery, descending thoracic aorta, and lower esophagus. However, the very proximal left mainstem is difficult to expose and requires mobilization of the arch by dividing the ligamentum arteriosum.⁴⁷

Repair of simple lacerations of the trachea and bronchi are repaired primarily using interrupted sutures of 3–0 polyglactin 910 (Vicryl) to reestablish mucosal-to-mucosal continuity. Débridement of devitalized tissues should be performed with caution to leave the greatest amount of trachea available for repair. Suture lines performed through the chest are reinforced with pedicled flaps of pleura or pericardium wrapped around the anastomosis. Alternatively, intercostal muscle can be used. Repairs made through the neck are reinforced using mobilized strap muscles. In the case of more complex injuries involving complete transection of the trachea, the trachea can be mobilized anteriorly and around the hilum to allow for structures to shift superiorly. Care is taken to avoid lateral dissection as much as possible, as the vascular supply enters on the sides. Interrupted 3–0 Vicryl sutures are placed after careful débridement. Pericartilaginous sutures are placed on the rigid portion of the trachea, and simple interrupted sutures are placed on the membranous portion (Fig. 22.1). At the end of the procedure, the patient’s chin may be sutured to the anterior chest to prevent the patient from extending the neck and stressing the suture line (“guardian stitch”). This stitch is left in for 1 week and removed after confirmation of integrity of the suture line is done by flexible bronchoscopy. Distal airway injuries associated with lobar destruction can be managed by lobectomy.⁴⁵ Stricture and dehiscence occur in 3% of patients following tracheobronchial reconstruction, with stricture often presenting as new-onset wheezing. If the stricture is limited, dilation and temporary stenting can allow remodeling and thus provide a permanently patent and functioning airway.

BLUNT CARDIAC INJURY

Blunt cardiac injury (BCI) encompasses a spectrum of pathology ranging from clinically silent transient dysrhythmia to deadly free wall rupture. BCI occurs most often from motor vehicle crashes⁴⁸ where rapid deceleration occurs. An alternative mechanism is a direct blow to the precordium. Any patient involved in a motor vehicle crash with sudden deceleration or who sustains significant chest trauma is thus at risk. Several forces may be involved in

BCI, including shearing from rapid deceleration, compression of the heart between the spine and sternum, abrupt pressure fluctuations in the chest and abdomen, and blast injury.^{49,50} The right heart is most commonly injured, likely related to its close proximity to the anterior chest wall and sternum.

The clinical features of BCI can vary widely. Most patients with severe BCI, such as uncontained myocardial rupture, do not reach the emergency department alive.^{51,52} Of those who do, hypotension may reduce pressure on the injured myocardium, which may rupture as fluid resuscitation restores blood pressure. Atrial rupture occurs far less often than ventricular rupture, most likely due to anatomy and lower compliance. Septal injury and isolated valvular injury are extremely rare. Of the valves, the aortic valve is most often injured, followed by the mitral and tricuspid valve. Depending on the valve involved and the degree of injury, the clinical presentation falls between acute valvular insufficiency with right- or left-sided heart failure, a widened pulse pressure, and a new cardiac murmur. Treatment of septal or valvular injury is surgical.

The most common and controversial form of BCI is cardiac contusion. The absence of a clear definition and accepted “gold standard” of diagnosis makes assessment of cardiac contusion difficult. The exact incidence is thus unknown, and can be difficult to determine in the multiply injured trauma patient with many reasons for hypotension. BCI often presents with other injuries. In one autopsy series, sternal fractures were found in 76% of cases involving cardiac injury.⁵³ However, a sternal fracture does not necessarily imply an associated BCI and lack of fracture does not rule out BCI.

Commotio cordis, a rare type of BCI in which low-impact trauma causes sudden cardiac arrest, usually occurs from being struck by a projectile during sports. The cardiac arrest is theorized to occur from the timing of the blow during a period of electrical susceptibility.

While BCI is often associated with thoracic trauma, it can occur in any patient with multisystem trauma. The ECG is the single most important screening test for hemodynamically stable patients with potential BCI. An ECG consistent with BCI may reveal persistent sinus tachycardia, another dysrhythmia, a new bundle branch block, or ST depressions or elevation. A screening ECG is obtained in all blunt trauma patients with chest pain or tenderness, history suggestive of heart disease, and active signs or symptoms consistent with heart disease. These may include signs of heart failure or abnormal heart sounds.

Patients with unexplained tachycardia that persists over several hours despite adequate fluid resuscitation and pain control, a new bundle branch block, or significant dysrhythmia are admitted for cardiac monitoring and echocardiography. Echocardiography can provide important information in a patient with BCI, but is not as important in the hemodynamically stable patient without dysrhythmia.^{49,54,55} In the rare case of blunt thoracic trauma with evidence of myocardial infarction on ECG, serial biomarkers should be measured (troponin I, creatine kinase [CK]-MB), and consultation done with both cardiology and cardiac surgery. In other patients without history of findings of severe cardiac injury but in whom concern persists, a brief course of ED observation over 6 hours can be done with a minimum of two ECGs obtained during the observation. Floor telemetry is appropriate for the patient with minor abnormalities (e.g., intermittent premature ventricular or atrial contractions), no significant concomitant injuries, and normal hemodynamics. All other patients should be admitted to the ICU for close monitoring, with associated cardiology consultation.

TRAUMATIC AORTIC DISRUPTION

Patients involved in high-energy blunt trauma involving rapid deceleration (such as a motor vehicle crash at speeds over 40 miles per hour or a fall from a height of 10 feet) are at signifi-

TABLE 22.3

CHEST RADIOGRAPHY FINDINGS ASSOCIATED WITH A MAJOR VASCULAR INJURY IN THE CHEST

- Widened mediastinum
- Obliteration of the aortic knob
- Deviation of the trachea to the right
- Depression of the left mainstem bronchus
- Elevation of the right mainstem bronchus
- Obliteration of the aortopulmonary window (space between the aorta and pulmonary artery)
- Deviation of the nasogastric tube (esophagus) to the right
- Widened paratracheal stripe
- Widened paraspinous interfaces
- Presence of a pleural or apical cap
- Left hemothorax
- Fractures of the first rib, second rib, or scapula

cant risk for blunt aortic injury (BAI). BAIs cause immediate death from aortic transection in 80%. In a minority of patients, the adventitia and mediastinal structures contain the rupture, allowing the patient to survive the ambulance transport to the ED. In patients who survive to reach the hospital, the most common site of disruption is just distal to the origin of the left subclavian artery at the ligamentum arteriosum. This site is the juncture of the mobile aortic arch and immobile descending thoracic aorta, additionally tethered by the intercostal arteries. In a sudden deceleration, the descending aorta stops with the rest of the body, while the heart and aortic arch continue to move forward. Shear force develops at the juncture of these two segments of aorta, creating a tear.⁵⁶

Specific signs and symptoms of traumatic aortic disruption are frequently absent. A high index of suspicion prompted by noting the mechanism of injury (rapid deceleration) and findings on chest radiography should be maintained, and the patient appropriately assessed. Findings on chest radiography that indicate a likelihood of major vascular injury in the chest are shown in Table 22.3. Any abnormality on chest radiography should be followed by a CT scan of the chest. A normal CT scan essentially rules out BAI.^{57–59} An equivocal CT scan should be followed by angiography to exclude aortic injury in those where suspicion of injury remains.⁶⁰ Transesophageal echocardiography (TEE) can be used in those patients too unstable for chest CT. TEE has a high sensitivity and specificity for BAI and can be performed either in the ED or in the OR. It also has utility in assessing valvular incompetence and pericardial effusions.

When BAI is diagnosed, the goal of management is to prevent propagation of adventitial dissection and subsequent free rupture by controlling the shearing forces exerted on the aorta. This is accomplished by lowering the heart rate with a beta-blocker and decreasing the blood pressure with intravenous nitroprusside or nitroglycerin in those cases where the beta-blocker alone is not sufficient. Intravenous esmolol, due to its rapid action and short half-life, is an ideal beta-blocker to use as an initial agent. Beta blockade should be initiated prior to any other blood pressure-reducing medications, as other drugs may result in a compensatory elevation in heart rate and thereby increase the shearing force. In patients in whom beta-blockers are contraindicated, a calcium channel blocker such as diltiazem can be used. The goal is to maintain a heart rate below 100 and a systolic blood pressure around 100 mm Hg.⁶¹

Surgical options include thoracotomy with open repair or interposition graft, and endovascular stenting. Surgery should not be delayed if clinical or radiographic signs of impending rupture are present such as reaccumulating hemothorax, rapid enlargement of a pseudoaneurysm, or contrast extravasation. Surgery should also ideally be done early in those patients who are hemodynamically stable without other major injuries, as

the risk of rupture is high if left untreated. There are, however, reports of patients who safely undergo delayed repair of BAI after diagnosis and careful management of wall stress.^{62–64} After controlling for comorbidities, these patients were found to have outcomes similar to those undergoing immediate repair. Many of these patients had other associated injuries that led to the delay in repair.

Paralysis is the dreaded complication of aortic reconstruction. Risk factors include preoperative hypotension, cross-clamp time (>30 minutes), and not using mechanical circulatory support.^{65,66} High mortality and paraplegia rates associated with open surgical intervention limit its utility. This led to the use of endovascular stents in BAI. The efficacy of stenting versus surgery in the emergent setting was specifically addressed in a nonrandomized study of 60 consecutive patients with acute rupture of the thoracic aorta; 28 patients were treated surgically and 32 were treated with an endovascular stent graft.⁶⁷ Findings of the study included a significantly lower perioperative mortality rate (3.1% vs. 17.8%). At a mean follow-up of 36 months, four additional deaths occurred in stented patients, three of which were attributed to late procedural complications (one aneurysm, one dissection, and one traumatic transection). No additional procedure-related deaths occurred in the surgical patients. Reintervention rates were similar in the two groups. All of the surgical reinterventions were early reexplorations for bleeding. In the patients treated with stents, one required early drainage of an empyema and two required late interventions for endovascular leaks (one repeat stent, complicated by paraplegia; one surgical repair with stent removal). Ongoing studies are awaited to assess the long-term durability of endovascular grafts.

TRAUMATIC DIAPHRAGMATIC INJURY

The true incidence of diaphragmatic injuries is hard to estimate because of missed and delayed diagnosis. A query of the National Trauma Data Bank (NTDB) of 952,242 patients from 565 trauma centers during the years 2000 to 2004 revealed an overall incidence of 0.63% ($n = 6,038$). Thirty-five percent occurred from blunt trauma and 65% from penetrating diaphragmatic injuries.⁶⁸ The frequency, however, may be even higher, as one prospective study where all patients admitted with left-sided penetrating thoracoabdominal trauma were evaluated with laparoscopy demonstrated 26 out of 110 (24%) patients with a diaphragmatic injury.⁶⁹

There are several possible mechanisms for diaphragm rupture: increased abdominal pressure from forceful impact that causes stretching with avulsion or, more commonly, lacerations; or fractured ribs that can perforate the muscle.⁷⁰ Tears tend to be in a radial orientation along the posterolateral aspect of the diaphragm. Diagnosis is easiest on the left when herniated bowel enters into the chest. Severe associated injuries occur in greater than 50% of cases. The liver and spleen are the most commonly associated injury. Diaphragmatic injury may be associated with epigastric and abdominal pain, referred shoulder pain, shortness of breath, or shock. However, some patients are asymptomatic, and initial chest radiography may be nondiagnostic, particularly if the patient is on positive-pressure ventilation. CT allows for the production of sagittal and coronal reformatting, which appears to improve accuracy. In one large series, the sensitivity for CT in diagnosing left-sided diaphragmatic tears was 78% and for right-sided tears was 50%, with 100% specificity.⁷¹ Accuracy is poor in the absence of visceral herniation. Right-sided injuries are more difficult to diagnose because the liver and diaphragm have a similar appearance on CT (Fig. 22.8). Coexisting injuries, atelectasis, and aspiration can also obscure the diaphragm and decrease sensitivity.

Often diaphragmatic injuries are found incidentally during laparotomy or thoracotomy to treat coexistent injuries. Treat-

ment is by direct repair whenever the injury is diagnosed; an “airtight” closure is not necessary, and excess tension and ischemia are to be avoided to prevent disastrous tissue loss in the difficult to mobilize diaphragm.

ESOPHAGEAL RUPTURE

Diagnosis, management, and outcome for traumatic esophageal perforations are affected by etiology, location, and duration between event and intervention. In trauma, there is a tendency for the diagnosis to be delayed.⁷² Esophageal injury lacks specific symptoms and generally occurs in multiple trauma, making it difficult to diagnose. Historically, injuries diagnosed greater than 24 hours after injury were treated with diversion. In recent times, the trend has changed to intervention based on the clinical stability of the patient, underlying esophageal pathology, and quality of the mediastinal tissues. There is now an emphasis on primary repair when possible, with some form of tissue reinforcement.

Traumatic injuries, which tend to involve the cervical esophagus in younger patients, have a mortality rate ranging from 9% to 19%.⁷² The most common traumatic injury occurs following penetrating neck injury, accounting for more than 80% of all traumatic perforations. Only 0.5% to 5% of penetrating neck injuries, however, are associated with esophageal involvement. Blunt trauma patients rarely sustain esophageal rupture; when they do occur, it is mostly in the cervical area, typically caused by a sudden blow to the anterior hyperextended neck. Virtually all thoracic traumatic perforations are a consequence of penetrating trauma. Transmediastinal gunshot wounds involving “low-velocity” missiles that course close to the spine can result in through-and-through injuries.

Signs of injury may include blood in the nasogastric aspirate, subcutaneous cervical air, and neck hematoma, but none is sensitive.^{72,73} Initial symptoms of cervical perforations may be simply hoarseness, spitting up blood, subcutaneous air, or anterior tracheal deviation. Untreated, fever, erythema, swelling, increasing crepitus, airway distress, and, finally, frank abscess formation occur. Infection often spreads along the precervical plane to involve upper mediastinal structures, leading to signs and symptoms of mediastinitis. Patients who present with zone II injuries that are associated with penetration of the platysma should be considered at risk for esophageal injury. Thoracic perforations typically have a subtle initial presentation but can quickly progress to mediastinitis, empyema, and septic shock.

Plain radiography may reveal pneumomediastinum, pleural effusion, mediastinal contour changes (which progress with inflammation), or gas bubbles in the nasogastric tube or esophagus, if a tracheoesophageal communication exists. CT scans may show subtle air leaks at the site of perforation, although the sensitivity of such findings is unclear. Pneumomediastinum without a clear cause is an indication for further assessment by a contrast study. Diagnosis is primarily made by contrast study. Although many radiologists favor Gastrografin studies, 15% of perforations can be missed with this type of study alone. Dilute or thin barium studies are thus preferred as the initial diagnostic study. A contrast study confirms the location of the leak and the side toward which the leak is going, and also demonstrates other pathology such as strictures that may need to be addressed.

Esophagoscopy and contrast studies are complementary in the trauma setting. Esophagoscopy can miss 15% to 40% of traumatic injuries, but when combined with contrast studies the sensitivity approaches 90% to 100%. Ideally, flexible esophagoscopy should be performed in the OR, as definitive intervention can be done when an injury is found.

The principles of surgical intervention include control of the leak, débridement of all devitalized tissues, wide drainage, and nutritional support. Broad-spectrum antibiotic coverage is essential.⁷⁹ Ideally, primary repair should be done whenever possible. Additional reinforcement with tissues such as pleura,

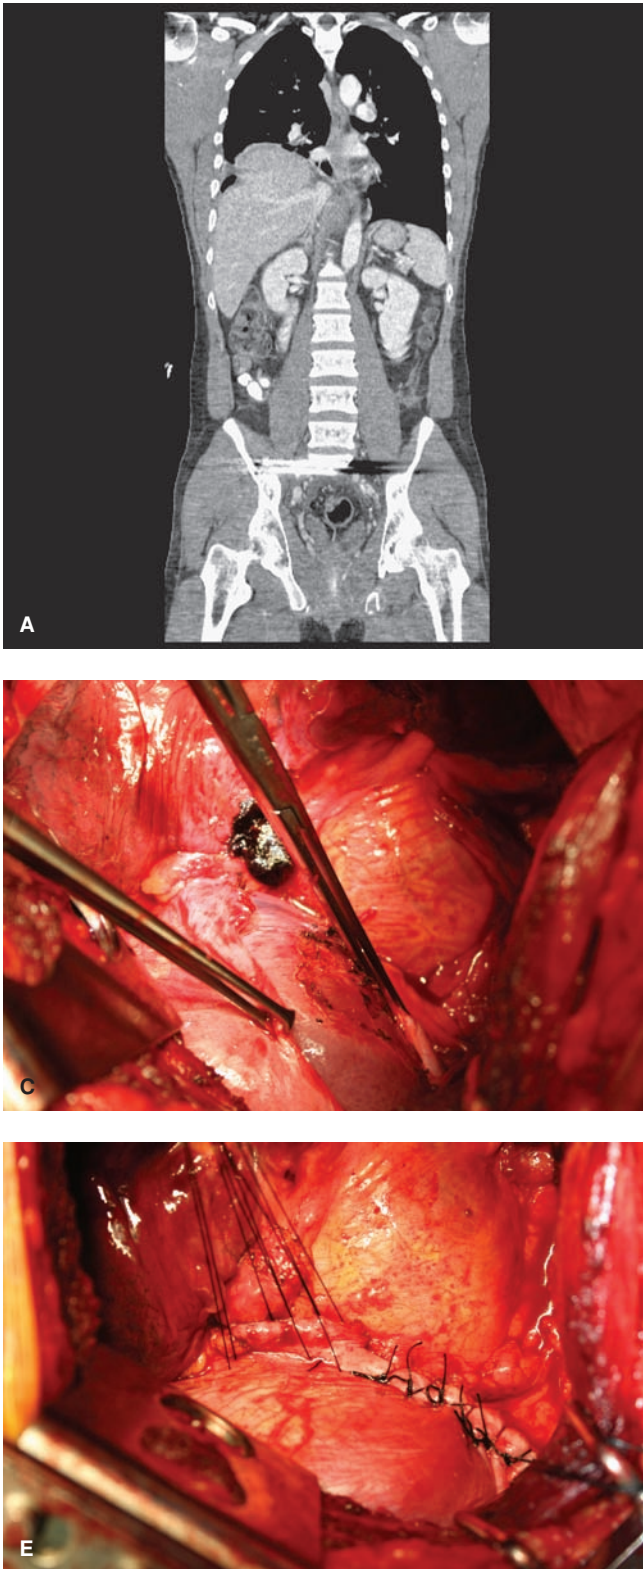

FIGURE 22.8. A: A 26-year-old male involved in a motor vehicle crash with acute rupture of the right diaphragm. Delay in diagnosis occurred in this patient, who had a normal-appearing chest radiograph. Computed tomography suggested the possibility of diaphragm hernia on sagittal reformats. B: Diagnosis initially made on video-assisted thoracoscopic surgery exploration, and conversion to open thoracotomy was performed for definitive repair. C: Exposure of free edges after adhesiolysis and taking down the inferior pulmonary ligament. D: Free edges of diaphragm tear reapproximated. E: Repair of diaphragm using interrupted no. 1 Surgilon sutures.

pericardial fat, diaphragm, or intercostal muscle should be used. In the cervical area, the sternocleidomastoid or other strap muscles can be mobilized as an onlay patch. When there is underlying preexisting esophageal pathology, the long-term results with primary repair are often poor, and hence esophageal resection may be needed in these cases. The presence of significant inflammation of tissues and/or degree of shock may mandate other approaches. In the setting of a delayed perforation, it is imperative that a thorough decortication is done to allow for adequate

lung expansion. Some authors feel that delayed perforations should be treated with diversions (cervical fistula or drainage with a T-tube). When the tear or perforation is very large, resection can be performed expeditiously. A long cervical esophagotomy can be brought out onto the anterior chest wall below the clavicle. This allows for better securement of an ostomy collection device over the stoma. This procedure has the advantages of being more comfortable for the patient and maximizing the length of residual esophagus for later reconstruction.

SPECIAL THORACIC TRAUMA ISSUES

Sternal Fractures

- 5** Because of the force required, the degree of sternal fracture displacement correlates with the risk for associated thoracic injury, although even nondisplaced fractures carry a significant risk.^{74,75} Commonly associated injuries include rib fractures, blunt cardiac injury, hemopericardium, spinal fracture, hemothorax, and pneumothorax. Sternal fractures usually result from a high-energy direct blow to the anterior chest wall. Typically these fractures occur during a motor vehicle crash when the driver's chest strikes the steering column or rapid deceleration causes an occupant's chest to slam against the cross-shoulder seatbelt.

As with rib fractures, management is primarily supportive. Most fractures are transverse, involve the sternal manubrial junction or upper one third of the sternum, and stabilize with pain control. Unstable fractures, fractures associated with chronic pain, or those associated with infection (indicated by new sternal click in the setting of fever or erythema) require operative intervention. Options include wires in figure-of-eight fashion, plates, or both (Fig. 22.9). Longitudinal fractures may require closure similar to that for closing a sternotomy incision. Sternal fractures complicated by mediastinal abscess may require serial widespread débridement and irrigation, followed by eventual closure with muscle or omental flaps.⁷⁶

Rib Fractures

Rib fractures represent the most frequent chest injury. Patients with three or more rib fractures, especially elderly patients, are

at significant risk for complications, such as pulmonary contusion and pneumonia, even in the absence of other injuries. In a multivariate analysis of 17,308 patients with rib fractures, age and Injury Severity Score were independent risk factors for development of pneumonia and mortality, with the incidence of pneumonia in this study being 6%, with an overall mortality of 4%.⁸⁰ These findings support the concept of aggressive pain management for patients with rib fractures to prevent atelectasis and to improve functional residual and vital capacity and the ability to clear secretions. Although the initial therapy for rib fractures has been supportive, the outcome of a strictly non-operative approach may at times not be ideal. Rib fracture repair has had waxing and waning enthusiasm among select centers for over 50 years, but the operative indications have not yet been clearly established. Potential indications for rib fracture repair include flail chest; painful, movable rib fractures refractory to conventional pain management; chest wall deformity/defect; rib fracture nonunion; and during thoracotomy for other traumatic indication.⁵ Rib fracture repair can at times be technically challenging secondary to the human rib's relatively thin cortex and its tendency to fracture obliquely. Many techniques of rib fracture repair have been described, including using wire sutures, intramedullary wires, staples, and various plates made of metal or absorbable materials (Fig. 22.10). Multicenter randomized trials are needed to firmly establish optimal guidelines in dealing with these common injuries.

Empyema

Posttraumatic empyema is likely to require surgical intervention because the blood and infection create a vigorous inflammatory reaction and early aggressive management of retained or contaminated hemothorax may reduce morbidity.^{77,78}

FIGURE 22.9. A: Computed tomography scan demonstrating transverse sternal fracture. B: Sternal plating performed using the titanium locking plates (Sternal Fixation System—Synthes CME, West Chester, Pennsylvania).

FIGURE 22.10. A: Exposure of rib fracture via cutdown technique. B: U-plate theoretically overcomes the inherent softness of the human rib by grasping the rib over its superior margin and by securing the plate with anterior-to-posterior locking screws that do not rely on screw purchase in bone (Acute Innovations Rib-Loc Plating System, Portland, Oregon). C: Securing the U-plate in place over the fractured rib. D: Final position of U-plate on fixed rib.

Patients with hemothoraces after chest tube placement with opacification of more than one-third hemithorax on chest radiography should be considered for drainage. Other risk factors include mechanical ventilation, splinting secondary to pain, hollow viscus injury, and chest tube placed in the emergency room. The primary reason that simple drainage or even thoracoscopic approaches may fail in treating empyema in the trauma population is the presence of a dense visceral peel preventing parenchymal reexpansion. Early and aggressive approaches including thoracotomy and formal pleurodesis are thus warranted in the trauma population.

SUMMARY

Thoracic trauma is common in the multiply injured patient and is a significant source of morbidity and mortality. The ability to recognize injuries in a timely manner can be lifesaving. The primary survey includes management of airway obstruction, tension pneumothorax, open pneumothorax, flail chest and pulmonary contusion, massive hemothorax, and cardiac tamponade. The secondary survey includes identification and initial treatment of potentially life-threatening injuries such as simple pneumothorax, hemothorax, pulmonary contusion, tracheobronchial tree injury, blunt cardiac injury, traumatic aortic disruption, traumatic diaphragmatic injury, and blunt esophageal injury. A deliberate and systematic approach in this patient population is essential in delivering effective care.

CHAPTER 23 ■ ABDOMINAL TRAUMA

DAVID H. WISNER, JOSEPH M. GALANTE, MATTHEW O. DOLICH, AND DAVID B. HOYT

KEY POINTS

- 1 To aid in the evaluation for injury, the abdomen can be divided into four areas: intrathoracic abdomen (diaphragm, liver, spleen, stomach), true abdomen (small and large intestines, distended bladder, gravid uterus), pelvic abdomen (rectum, bladder, urethra, small intestine, female reproductive organs), and retroperitoneal abdomen (kidneys, ureters, pancreas, second and third duodenum, aorta, vena cava). With the exception of the true abdomen, all of these areas are difficult to assess by physical examination alone.
- 2 The top three patterns of injury are liver, intestines, and spleen caused by blunt (usually vehicular crashes, vehicle vs. pedestrian, and falls) and penetrating (gunshot and shotgun) trauma.
- 3 Adjunctive assessment is critical using hematocrit; white blood cell count; biochemical markers (amylase, lipase, creatinine, bilirubin, liver function tests); imaging, including ultrasound (focused abdominal sonography for trauma [FAST]), computed tomography (CT), and angiography; and diagnostic peritoneal lavage (DPL), as indicated by mechanism, pattern, and risk.
- 4 The objective is to determine who needs an operation—not what organ is injured. The primary effect of solid organ injury is bleeding (monitored by hematocrit and FAST, DPL, or CT), and visceral injury, peritonitis (diagnosed by physical examination, laboratory, DPL, and, increasingly, CT).
- 5 Operative treatment of specific injuries is dictated by pattern, extent, and overall stability of the patient and associated injuries. Blunt and penetrating injuries are, in large part, treated by similar principles. Grossly unstable patients require a “damage control” approach and return on a later day, when stable.
- 6 Specific pattern of injury (e.g., lower abdominal lap belt bruising along with lumbar spine fracture) may indicate need for operative intervention for intestinal injury and should be recognized early to minimize morbidity.
- 7 Approach to retroperitoneal hematoma depends on cause, location, and other injuries. The retroperitoneum is divided into zones to aid decision making: central (zone 1) is associated with pancreaticoduodenal injuries or major vascular injury and must be explored; flank (zone 2) is associated with perinephric bleeding and injuries are explored if enlarging, pulsatile, or caused by penetrating trauma; and pelvic (zone 3) is associated with pelvic fractures, entered at great risk, and best left alone.

Within the broad scope of trauma care, the knowledge to comprehensively manage abdominal trauma is the sine qua non of the trauma surgeon. Most civilian abdominal injuries are caused by blunt trauma secondary to high-speed automobile crashes, although penetrating injuries are common in urban environments. The inability to appropriately manage abdominal injuries accounts for most of the preventable deaths that follow multiple trauma. Failure to recognize occult abdominal hemorrhage and to control bleeding from intra-abdominal organs leads to significant morbidity, and such injuries account for approximately 10% of the traumatic deaths that occur annually in the United States.

ANATOMIC CONSIDERATIONS

The abdomen is defined by the diaphragm at its superior aspect and by the infragluteal fold at its caudal aspect; it includes the entire circumference of the torso. Abdominal injury is often accompanied by trauma to other sites, such as the central nervous system, the chest, and the musculoskeletal system. The pattern of extra-abdominal injury can often predict the abdominal organs at risk of injury. To simplify the initial trauma evaluation, the abdomen can be divided into four areas: intrathoracic abdomen, true abdomen, pelvic abdomen, and retroperitoneal abdomen (Fig. 23.1). With the exception of the true abdomen, all of these areas are difficult to assess by physical examination alone.

The intrathoracic abdomen is the portion of the upper abdomen that lies beneath the rib cage (Fig. 23.1A). Bony and

cartilaginous structures make this area essentially inaccessible to palpation. Its contents include the diaphragm, liver, spleen, and stomach. Each of these organs can be injured when blunt or penetrating impact is delivered to the rib cage.

The pelvic abdomen is defined by the bony pelvis (Fig. 23.1B). Its contents include the rectum, bladder, urethra, small intestine, and, in female patients, the uterus, fallopian tubes, and ovaries. Trauma to the pelvis, particularly pelvic fractures, can damage the organs within, while penetrating injuries of the buttocks can injure any or all of the pelvic organs. Injury to these structures may be extraperitoneal and, therefore, difficult to diagnose. For this reason, suspected injuries may require adjunctive procedures such as bladder catheterization, urethrocystography, and sigmoidoscopy for diagnosis.

The retroperitoneal abdomen contains the kidneys, ureters, pancreas, second and third portions of the duodenum, great vessels, aorta, and vena cava (Fig. 23.1C). Injury to these structures can occur secondary to penetrating or blunt trauma. The kidneys can be damaged by injury to the lower ribs posteriorly, and any of these structures can be damaged by crushing injuries to the front or side of the torso. Again, injury to these structures may result in few physical findings, and physical examination and diagnostic peritoneal lavage (DPL) are of little use. Accurate evaluation of the retroperitoneal abdomen usually relies on computed tomography (CT), angiography, and ultrasound.

The true abdomen contains the small and large intestines, the bladder when distended, and the uterus when gravid. Perforation of these organs is usually manifested by pain from peritonitis and is associated with significant abdominal physical

FIGURE 23.1. Four traditional anatomic divisions of the abdomen. **A:** Intrathoracic abdomen. Contents of this area are subdiaphragmatic but cephalad to the costal margin. With respiration, the diaphragm is presumed to ascend to the level of the nipples (fourth intercostal space anteriorly). A ruptured left hemidiaphragm is illustrated with herniation of the stomach and distal transverse colon into the left hemithorax. **B:** Similarly, the contents of the pelvic abdomen are within the bony pelvis. **C:** The structures in the retroperitoneal abdomen. The true (intraperitoneal) abdomen contains the remainder of the viscera, and the inventory of its contents is dynamic, depending on body position and respiration (not shown).

findings. While CT will usually provide substantial evidence when a solid organ injury is present, DPL can be a useful adjunct if intestinal injury is suspected.

The unique anatomy of the pediatric abdomen can substantially influence the pattern of injury. The high costal margin and low pelvic brim increase the amount of unprotected abdominal organs relative to the rest of the body. The thin abdominal musculature, diminished fat pad, and pliable ribs all contribute to vulnerability of the abdominal organs to trauma.

PENETRATING INJURY

- 2 While stab wounds are more common, handguns are more likely to cause serious penetrating injury to the abdomen. Significant intra-abdominal injury occurs in approximately 80% to 90% of patients who sustain abdominal gunshot wounds but in only 20% to 30% of patients with stab wounds. The difference in injury potential between gunshot wounds and stab wounds is a function of both depth of penetration and the higher kinetic energy associated with gunshot wounds. Selective management may be the best method for treating stab wounds. The frequency of organ injury after penetrating abdominal trauma is shown in Table 23.1.

Injuries to both thoracic and abdominal cavities occur in 25% of patients with penetrating wounds of the abdomen. Patients with penetrating wounds of the thorax also may have significant intra-abdominal injury because a bullet or knife can readily traverse the diaphragm. Patients with gunshot wounds to the abdomen and lower chest may routinely undergo laparotomy because the probability of intra-abdominal injury is high. Nonetheless, in patients where the trajectory may be tangential to the peritoneum or may have only traversed the liver, CT may be considered to allow the option of nonoperative management.

BLUNT TRAUMA

Automobile crashes are the cause of at least 60% of all traumatic injuries. Table 23.2 shows the frequency with which

specific organs are injured by blunt abdominal trauma. Some series list the liver rather than the spleen as the most commonly injured intra-abdominal organ; this difference probably reflects the means of diagnosis. Small liver injuries are often detected in patients who undergo CT scan of the abdomen, whereas splenic injuries in adults are more likely to be clinically significant and to require surgical intervention.

Solid organs are most frequently injured from blunt trauma. The sudden application of pressure to the abdomen is more likely to rupture a solid organ than a hollow viscus. The more elastic tissues of young people tolerate trauma better than those of older people, and this accounts in part for the differences in incidence and pattern of injuries between children and adults with blunt abdominal trauma.

PREHOSPITAL CARE

Little can be done outside a hospital for patients with abdominal injuries. For penetrating wounds, sterile dressings should be applied and the patient should be carefully monitored. Foreign bodies embedded in the trunk should not be removed because major bleeding can follow. Evisceration is best left undisturbed except for application of a moist sterile dressing and protection of the eviscerated organ from further injury. General principles of stabilization and evaluation should be followed, including ensuring an adequately functioning airway, inserting intravenous lines (preferably in the upper extremity), beginning fluid resuscitation, and providing rapid transport to a trauma center. Recent controversy surrounding the issue of the value of fluid resuscitation in the early posttraumatic period has arisen. In blunt trauma, aggressive volume resuscitation to return toward normal vital signs and level of consciousness is generally indicated, though a preoccupation with fluid resuscitation at the scene should not delay rapid transport to a trauma center. In penetrating abdominal trauma, smaller resuscitation volumes to achieve a systolic blood pressure only greater than 70 to 80 mm Hg may improve outcomes and diminish total blood loss.¹ The prehospital application of the pneumatic antishock garment in the treatment of abdominal trauma is rarely indicated and may lead to increased blood loss from injury manipulation and delay in transfer and impair pulmonary and cardiac function due to upward pressure on the diaphragm and increase in afterload.

HOSPITAL RESUSCITATION AND DIAGNOSIS

Diagnosis and treatment should proceed concurrently according to established protocols. A functioning airway must be established, particularly in the comatose patient, before evaluation of the abdomen occurs. If necessary, an endotracheal tube is placed and assisted ventilation is begun. Upper extremity, large-bore intravenous catheters are initiated, and resuscitation is begun with a balanced salt solution (e.g., lactated Ringer or normal saline). Early crystalloid resuscitation is mandatory, especially in the presence of a head injury, despite theoretic considerations that instillation of intravenous fluids increases bleeding and causes a dilutional coagulopathy.² When operative intervention is indicated, however, it should not be delayed by overzealous and prolonged attempts at fluid resuscitation.

HISTORY AND PATTERN OF INJURY

Penetrating injuries present little diagnostic challenge other than the question of whether to explore the abdomen operatively. An attempt should be made to establish details of the trauma event and the weapon used. The blunt trauma assessment can be aided considerably by an accurate history. If the patient was involved in an automobile crash in which he or she struck the steering wheel or if no seatbelt was used, specific thoracic and epigastric abdominal trauma should be suspected. If the patient was restrained, it can be helpful to determine whether the restraint was a two-point lap belt or a three-point shoulder belt. The patient who sustains rib fractures involving the lower left chest has a 15% chance of associated splenic injury; the patient with rib fractures on the right has a 10% chance of liver injury. A compression fracture of the lumbosacral region carries a 20% risk of significant renal parenchymal injury.

PHYSICAL EXAMINATION

The objective of the physical examination in abdominal trauma is to rapidly identify the patient who needs laparotomy. Precise definition of specific organ injury is unnecessary. In addition, the specificity and sensitivity of physical examination alone, however, are not adequate to make these determinations. Associated injuries often cause tenderness and spasm in the abdominal wall and make diagnosis difficult. Lower rib fractures, pelvic fractures, or abdominal wall contusions can mimic the signs of peritonitis.

In patients with gunshot wounds, no presumptions should be made about entrance and exit wounds. Unfounded presumptions can lead to inaccurate estimations about the number of times a patient was shot and the course of the bullets. If time permits, radiographs should be obtained to determine the location of any bullets or bullet fragments that remain in the patient. Penetrating wounds should be marked with radiopaque clips to allow radiographic delineation of the injury tract.

Because the primary manifestation of blunt solid organ injury is hemorrhage, the patient should be monitored closely during the initial assessment, and continuing or refractory shock is presumed to result from continuing or massive hemorrhage. The patient should be examined from head to toe for signs of blunt trauma and for penetrating wounds. Small abrasions or areas of ecchymosis suggest significant local intra-

abdominal injury. The abdominal wall and back should be carefully inspected, and posterior ecchymosis should raise the possibility of retroperitoneal injury. The absence of bowel sounds is consistent with an ileus, but it is a nonspecific finding and, in the context of a busy emergency department, it is insensitive for discriminating between patients who do and do not need laparotomy.

Palpation can reveal localized tenderness, spasm, or rigidity of the abdominal wall. These findings and the finding of rebound tenderness are consistent with peritonitis and perforation of hollow viscera. Exploratory laparotomy is required for this presumed diagnosis. Suprapubic tenderness and pelvic lateral wall tenderness, which can indicate a pelvic fracture, are assessed in the conscious patient. Inspection of the perineum and urethral meatus for blood is routine to look for signs of pelvic fracture and possible urethral injury.

As assessment continues, rectal examination is performed and sphincter tone is evaluated. The integrity of the rectal wall and the position and excess mobility of the prostate associated with urethral injury are evaluated. The stool should be tested for the presence of gross or occult blood. A urinary catheter is placed, and a urine sample is sent for analysis for microscopic hematuria. If injury to the urethra is suspected, retrograde urethrography (RUG) should be performed before attempted catheterization and possible aggravation of injury and a suprapubic catheter placed if necessary.

The physical findings for injuries to these different structures are sometimes a function of the time between injury and examination. Hollow viscus perforations may require several hours before peritonitis becomes apparent. Colonic or gastric perforations produce peritonitis more rapidly, small bowel perforations less so. Hematomas and bruising from retroperitoneal or pelvic fracture bleeding may not be apparent initially. Frequent reevaluation is an essential strategy in the nonoperative treatment of patients with blunt abdominal trauma.

LABORATORY STUDIES

3 The hematocrit is the primary blood study of value in the initial evaluation of a patient with abdominal trauma. Leukocyte counts, serum creatinine, glucose, serum amylase/lipase, and serum electrolyte determinations are often obtained for reference but usually have little value in the immediate management period, but are critical for serial assessments and trending the results.

The diagnosis of massive hemorrhage is usually obvious from hemodynamic parameters, and the hematocrit merely confirms the diagnosis. Iatrogenic dilutional anemia is common and, in the presence of hemodynamic stability, is well tolerated. In the less severely injured, serial hematocrits showing a persistent downward trend identify ongoing bleeding requiring operative or angiographic intervention. Urinalysis confirms the presence of microscopic hematuria. For blunt trauma, radiographic evaluation (usually by CT) of the kidneys and bladder should be initiated if the patient has gross hematuria or microscopic hematuria and shock (systolic blood pressure <90 mm Hg in an adult) at any point during the prehospital or emergency department course.

The serum amylase is insensitive and nonspecific as a marker for major pancreatic or enteric injury. Injuries to the head and face commonly cause increased plasma amylase concentrations. Serum lipase levels are not elevated by facial trauma and are possibly more specific than amylase levels. Sensitivity and specificity of lipase levels, however, especially in the early postinjury period, are still relatively low. Sensitivity and specificity of both the amylase and lipase improve with

serial testing. Persistent or increasing elevations of the amylase or lipase should, therefore, raise concern of significant intra-abdominal injury and are an indication for aggressive radiographic or surgical investigation.

RADIOGRAPHIC EVALUATION

Radiologic studies of potential value in the evaluation of abdominal trauma include a chest radiograph, retrograde urethrography and cystography, CT scans, ultrasound, and angiography. In addition, all injuries from penetrating trauma should be evaluated with a plain radiograph with the use of radiodense markers on the wound sites to allow evaluation of the missile trajectory. With blunt trauma, an anteroposterior film of the pelvis can delineate pelvic fractures not detectable on physical examination. The initial pelvic film or chest radiograph can also demonstrate fractures of the thoracic or lumbar spine. A transverse fracture of the vertebral bodies, or Chance fracture, should increase the search for serious blunt intestinal injury. The value of plain abdominal films after blunt trauma is extremely limited and they should not be routinely obtained.

4 Of greater value are CT scans, ultrasound, and angiography. CT has real value in the accurate assessment of solid organ injuries, particularly of the liver, kidney, and spleen; contrast-enhanced CT has great accuracy in the delineation of intra-abdominal bleeding. The accuracy of CT scan in evaluation of hollow viscus injury is somewhat more limited, but improvements in CT technology have led to increasing sensitivity of CT in the detection of the more subtle signs of injury to the intestine.^{3,4} CT is also highly specific in the evaluation of retroperitoneal injuries and is the single most useful and informative diagnostic study for patients with abdominal trauma.

CT scanning can also be used on occasion for penetrating injuries when it is uncertain whether the track of the knife or bullet violated the retroperitoneum or the peritoneal cavity. Such an approach is most useful in patients with back and flank wounds but is also occasionally helpful in patients with anterior wounds if it is likely that the knife did not reach the peritoneal cavity or the bullet traversed a tangential path. Patients with any signs of peritonitis or hemodynamic instability after penetrating trauma are obviously not candidates for diagnostic CT scanning, nor is any trauma patient displaying hemodynamic instability.

Angiography is reserved for specific situations, such as suspected aortic or renal arterial injuries, or ongoing hemorrhage from pelvic, hepatic, or splenic injuries. It is not considered an initial screening investigation.

Laparoscopy has been used for both diagnosis and treatment of trauma patients.⁵ Although limited to evaluation of the diaphragm in blunt trauma, after penetrating trauma laparoscopy is helpful when it is unclear whether the peritoneum has been penetrated. In patients in whom peritoneal penetration is seen, the use of laparoscopy to further explore the peritoneal cavity and repair injuries is more controversial. The adequacy of abdominal exploration, particularly examination of the bowel and retroperitoneum, has been questioned, and repair of large injuries through the laparoscope can be tedious. In patients with a lower chest wound, however, laparoscopy can identify both peritoneal penetration and diaphragmatic injury. An isolated diaphragmatic injury or associated nonbleeding liver laceration is one area in which repair of the diaphragm through the laparoscope has proved feasible. Of note, when laparoscopy is used in patients with potential diaphragmatic injury, the positive pressure in the peritoneal cavity can lead to tension pneumothorax if the chest is not adequately vented.

DIAGNOSTIC PERITONEAL LAVAGE AND ABDOMINAL ULTRASOUND

Diagnostic peritoneal lavage and focused abdominal sonography for trauma (FAST) are standard techniques to detect significant intra-abdominal hemorrhage after blunt trauma. FAST is less useful after penetrating trauma for potential intestinal injury.

The specific indications for DPL or FAST in blunt trauma include the following:

- Unconscious patient with question of potential abdominal injury
- Patient with a high-energy injury, suspected intra-abdominal injury, and equivocal physical findings
- Patient with multiple injuries and unexplained shock
- Patient with major noncontiguous or thoracoabdominal injuries
- Patient with spinal cord injury
- Intoxicated patient in whom abdominal injury is suspected
- Patient who has a suspected intra-abdominal injury with equivocal diagnostic findings and who will be undergoing prolonged general anesthesia for another injury, making continued reevaluation impossible

Relative contraindications to DPL but not to FAST are previous abdominal operations, pregnancy, and morbid obesity. Obvious peritonitis is a contraindication to either study. If the patient is hemodynamically stable, CT scan is prudent, and if the patient is unstable, immediate exploratory laparotomy, rapid abdominal tap, or FAST to confirm gross hemoperitoneum is indicated.

Diagnostic peritoneal lavage is not generally useful for patients with abdominal gunshot wounds, most of whom require laparotomy.⁶ If local exploration of a stab wound suggests penetration of the fascia or peritoneum, DPL can help distinguish significant and insignificant injuries. It is most sensitive in the diagnosis of hemoperitoneum, but significant hemoperitoneum does not necessarily accompany hollow viscus lacerations. In blunt trauma, DPL is considered positive if 10 mL of grossly bloody aspirate is obtained before instillation of lavage fluid or (of much less importance) if the siphoned lavage fluid has more than 100,000 red blood cells (RBCs) per milliliter (equal to 20 mL of blood). Evaluation of lavage fluid in stab wounds should be based on a more sensitive protocol. In general, more than 1,000 RBCs/mL is considered a positive DPL, and laparotomy should follow. In both cases, presence of bile, amylase, bacteria, or particulate matter should indicate visceral injury and need for laparotomy.

Diagnostic peritoneal lavage and CT scan are both satisfactory tests for the diagnosis of visceral injury after blunt abdominal trauma. DPL has some advantages, including rapidity, higher sensitivity, lower cost, and immediate interpretation (Table 23.3). The major disadvantages are a 1% to 3% risk of iatrogenic intraperitoneal injury and the high sensitivity of the test. The high sensitivity can lead to nontherapeutic laparotomies (i.e., when there are no injuries requiring repair). False-positive DPL findings may result from traversing a pelvic hematoma that has dissected into the anterior infraumbilical abdominal wall if an infraumbilical approach is used in a patient with a pelvic fracture. A pelvic radiograph should be obtained before DPL, and if a pelvic fracture is present, the incision is placed cephalad to the umbilicus.

Before DPL, the bladder should be emptied with a Foley catheter. The abdomen is prepared with povidone-iodine solution and draped with sterile towels. The infraumbilical midline is infiltrated using lidocaine with epinephrine, and a 3-cm incision is carried down to the linea alba. This is opened, and a peritoneal

TABLE 23.3**DIAGNOSIS**

COMPARISON OF DIAGNOSTIC PERITONEAL LAVAGE AND COMPUTED TOMOGRAPHY IN THE DIAGNOSIS OF VISCERAL INJURY AFTER BLUNT ABDOMINAL TRAUMA

	■ DIAGNOSTIC PERITONEAL LAVAGE	■ COMPUTED TOMOGRAPHY
False-negative result	<1%	5%–20%
False-positive result	5%–12%	5%
Time to complete	5 min	55 min
Cost	\$125	\$900

dialysis catheter is placed through the peritoneum under direct vision. After peritoneal entry, the catheter is directed at a 45-degree angle into the pelvis and aspirated. If the aspirate returns 10 mL of bloody fluid, the study is considered positive and is terminated. If little or no blood is aspirated, 1,000 mL of warm normal saline (or 10 mL/kg in a child) is rapidly infused into the peritoneal cavity. After the infusion is complete, the empty intravenous bottle is placed on the floor, allowing the intraperitoneal fluid to be siphoned into the bottle for analysis.

Ultrasound (FAST) has become increasingly popular in the initial diagnostic management of abdominal trauma and, when available, can be used in the circumstances outlined earlier for DPL.⁷ FAST has been used as a screening modality for all patients with blunt trauma to determine which stable patients should undergo further diagnostic imaging with CT scanning.^{8–10} It has also been used in hemodynamically unstable patients to rapidly determine the presence of intraperitoneal fluid and the need for immediate surgery analogous to the use of gross blood on DPL.¹¹

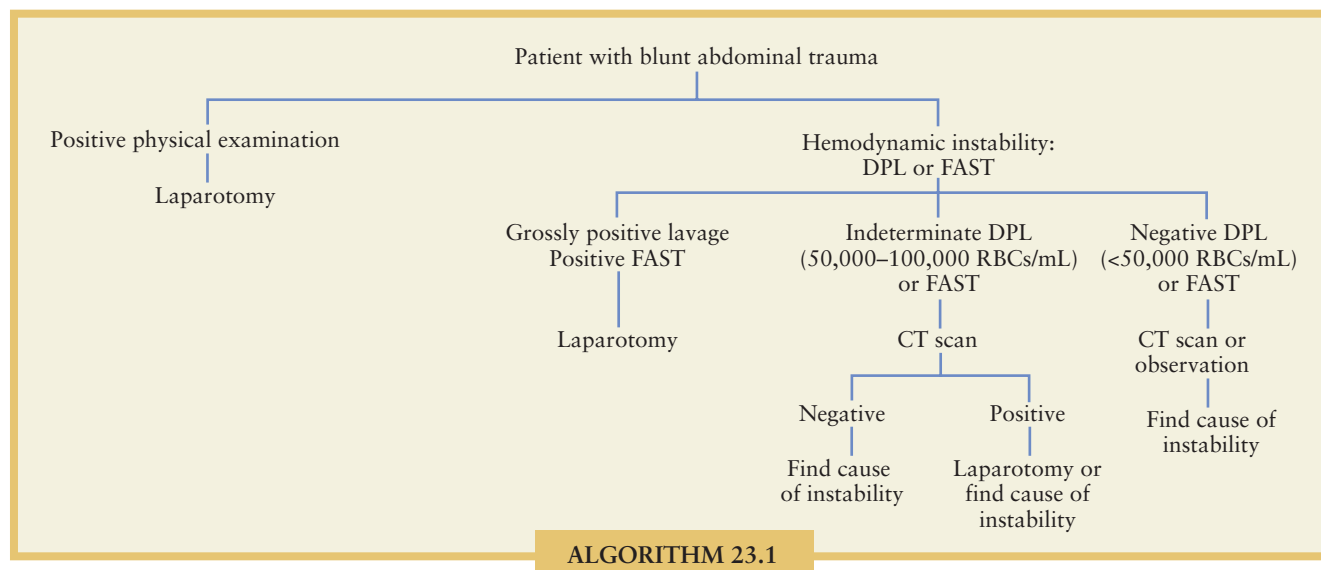

In FAST, the ultrasound probe is used to interrogate serially the subhepatic space, the pericolic gutters, the left upper quadrant, the pericystic area in the pelvis, and the pericardial space. A small amount of physiologic fluid is occasionally seen in the pelvis, but anything more should be considered abnormal and should prompt either operative exploration or further investigation.

There is a steep learning curve for the use of FAST in the emergency department, but in the hands of experienced personnel it is effective in determining the presence or absence of intraperitoneal blood. Emergency department ultrasound is not very sensitive for the identification of specific organ injuries and is insensitive for the diagnosis of bowel injuries. It has proved much better for the evaluation of blunt trauma than for penetrating trauma, although interrogation of the pericardial space with an ultrasound probe placed in the subxiphoid position is sensitive for the presence of pericardial blood in patients with potential penetrating cardiac injuries.

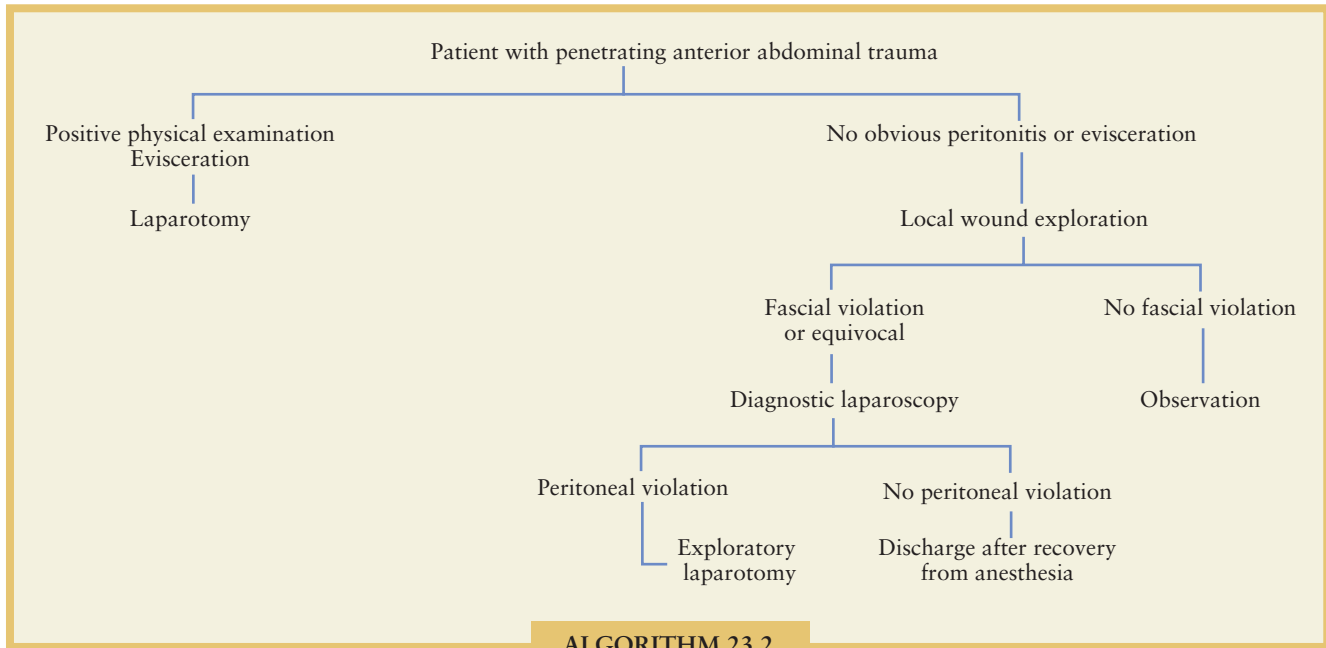

The general approaches to the diagnosis of blunt and penetrating trauma are outlined in Algorithms 23.1 and 23.2.

INDICATIONS FOR SURGERY

It is the job of the general surgeon directing a trauma team to integrate the various specialties involved in the care of the multiply injured patient. Judgments about specialized procedures for problems that are not life threatening need to be made with an overall view of the patient's physiologic status. Indications for laparotomy include signs of peritonitis, evisceration, clinical deterioration during observation, and, in the presence of

ALGORITHM 23.1. Diagnosis of blunt abdominal trauma.

ALGORITHM 23.2. Diagnosis of low-velocity penetrating abdominal trauma.

hemodynamic instability, a DPL or FAST examination consistent with hemoperitoneum.

Broad-spectrum antibiotics are given as soon as the decision to perform a laparotomy is made. The spectrum of coverage should include anaerobic, in addition to aerobic, including gram-positive cocci, organisms. Good evidence suggests that antibiotics do not need to be continued for longer than 24 hours postoperatively, even if contamination from an injured hollow viscus has occurred.^{12,13} Tetanus prophylaxis should be administered. If fully immunized as a child, a patient is adequately treated with a booster immunization. If adequate childhood immunization is absent, unlikely, or unknown, then passive immunization should be provided with hyperimmune globulin.

OPERATIVE APPROACH

The patient should be placed supine on the operating room table and the entire anterior torso from the sternal notch to the middle thighs should be prepared and draped to allow for maximum exposure and harvesting of the saphenous vein, if necessary for vascular repair. A midline incision is preferred and there are few reasons to deviate from this choice. This incision also allows extension into a median sternotomy in the event that more proximal control of the vena cava is needed or if the patient is found to have a cardiac injury.

After the abdomen is opened, obvious blood and clot are removed, and packing of the four quadrants is accomplished as indicated by ongoing bleeding. If the peritoneal cavity is full of blood, the location of clot is often a clue to the site of bleeding. Inflow occlusion can be accomplished, if needed, by clamping the aorta at the diaphragmatic hiatus adjacent to the esophagus. Obvious hollow viscus wounds should be rapidly controlled by sutures, clamps, or staples. This initial closure does not need to be definitive and is done primarily to minimize contamination during the course of the operation. Retroperitoneal bleeding may be the source of exsanguinating hemorrhage if rupture into the free peritoneal cavity has

occurred. If not, these hematomas can be left for investigation at a later time, depending on their location. Hematomas of the pelvis that are associated with pelvic fractures should not be disturbed. Stable hematomas in the perinephric space lateral to the midline are also best left undisturbed. Central hematomas that can involve injury to the major vascular structures, pancreas, or duodenum are noted and explored after control of injuries within the peritoneal cavity.

After packing has controlled hemorrhage and ongoing contamination has been stopped, time is taken to allow resuscitation of the patient's circulating blood volume. Warming is necessary if massive blood loss has occurred and all fluids must be infused through warming devices, such as the level I. Sustained periods of hypotension should be avoided at all costs, which usually can be accomplished with packing. A complete and thorough exploratory laparotomy is performed methodically to investigate the entire contents of the abdomen for occult injuries.

In some patients, a temporizing approach to intra-abdominal injuries, or "damage control," is appropriate.¹⁴ Minimizing operative time is emphasized and the definitive management of all injuries is not necessary. Appropriate candidates for damage control laparotomy are patients with profound coagulopathy, severe acidosis, hypothermia, massive intra-abdominal injuries, or severe associated nonabdominal injuries. Hollow viscus injuries should be temporarily controlled to prevent ongoing contamination, but restoration of gastrointestinal continuity is not performed. The abdominal wall is routinely left open either because of excessive tension and/or need to reoperate for definitive repair, and resuscitative efforts are continued with particular emphasis on correcting coagulopathy, acidosis, and hypothermia. A variety of techniques are available to temporarily avoid abdominal wall closure and still adequately cover and protect the abdominal viscera. Temporary vacuum dressing of the abdominal wall with plastic sheets, dressings, suction drains, and Ioban drapes or similar commercial devices has shown promise as a means of protecting the viscera while maintaining the pliability of the abdominal wall to allow for later fascial closure.¹⁵ A

planned reoperation is then undertaken when the patient's condition permits and definitive injury repair is undertaken at that time.

SPECIFIC INJURIES

Diaphragm

Injuries to the diaphragm after blunt trauma involve predominantly the left hemidiaphragm. All diaphragmatic injuries must be repaired to avoid the long-term potential for herniation, incarceration, and strangulation of abdominal viscera. Strangulation can occur months or even years after the injury if the hole in the diaphragm is not diagnosed and treated. The diagnosis of diaphragm injury should be suspected if respiratory distress and radiologic evidence of pleural effusion are not relieved by tube thoracostomy or if an upright radiograph demonstrates obvious visceral herniation into the thorax (Fig. 23.2). Chest radiograph (CXR) findings in patients with blunt diaphragmatic rupture are sometimes subtle, particularly in the face of positive-pressure ventilation, and may appear only as a blurring of the costophrenic angle or the line of the hemidiaphragm. Serial CXRs may demonstrate evidence of delayed herniation. Low-thoracic (below the level of the nipples) penetrating injuries should be presumed to have traversed the diaphragm. During exploratory laparotomy, the entire diaphragmatic surface should be exposed and directly visualized. Linear lacerations can be repaired with a simple running suture or interrupted horizontal mattress sutures, whereas larger lacerations and tissue deficits occasionally require repair with prosthetic material or resuspension of the diaphragm to higher ribs. Exploration of acute traumatic diaphragmatic rupture is usually accomplished through the abdomen because of the high risk for associated intraperi-

FIGURE 23.2. Chest radiograph showing gastric bubble in the left chest consistent with a rupture of the left hemidiaphragm.

toneal injury and because the lack of adhesions makes reduction of the abdominal viscera back into the peritoneal cavity relatively easy. Defects discovered at a later date can be addressed satisfactorily by a transthoracic approach, which facilitates lysis of adhesions.

Spleen

Splenic injury is often heralded by lower rib fractures on the left because the spleen lies in the left upper quadrant just to the left and slightly posterior to the stomach. The history is helpful if the patient describes a direct blow to the left chest, flank, or abdomen. For penetrating trauma, a wound entry or exit in this area should raise the suspicion of splenic injury. The clinical signs may be few and subtle; a high level of suspicion must be maintained simply on the basis of mechanism of injury. Clinical evidence of splenic injury includes signs of blood loss, left upper quadrant abdominal pain or tenderness, and pain referred to the left shoulder (Kehr sign) from diaphragmatic irritation.

In general, laboratory studies are of limited help. CT scan is useful in hemodynamically stable patients for demonstrating splenic injury. Ultrasound can confirm hemoperitoneum, if present, with splenic injury.

Historically, splenic injury was routinely treated with splenectomy. During the last few decades, several factors have contributed to a change in this management strategy. Post-splenectomy sepsis, with its high attendant mortality rate, has been characterized, particularly in the treatment of children. In addition, the relative success rates for splenic salvage techniques and nonoperative management have been well established. Nonoperative approaches focus on the clinical presentation of the patient rather than the CT scan appearance, although the presence of a “blush” on the CT scan is indicative of potential ongoing bleeding and an increased likelihood of need for operative intervention¹⁶ (Fig. 23.3). The presence of a “blush” has also been used as a trigger for angiographic embolization in hemodynamically stable patients to prevent ongoing or recurrent bleeding. Care should be exercised to not confuse a nonbleeding pseudoaneurysm with a “true blush” of ongoing bleeding. Although increasingly practiced, nonoperative management is not without dangers and limitations. Potential disadvantages include a more prolonged hospitalization and possibly more exposure to transfused blood, but the

FIGURE 23.3. A cut from a computed tomography scan through the upper abdomen of a patient with a splenic injury. The spleen has evidence of several areas of contrast “blush.”

principal risks are ongoing hemorrhage and missed associated intra-abdominal injuries, particularly to the pancreas or bowel.

The spleen is evaluated for hemorrhage during the course of laparotomy. If hemorrhage is noted, a decision must be made regarding splenic salvage. This assessment requires complete mobilization of the spleen from its lateral and posterior attachments, and care must be taken to prevent further injury. The spleen and tail of the pancreas must be mobilized together to evaluate adequately the extent of splenic injury. Ongoing bleeding is controlled during mobilization by manual compression. Topical hemostatic agents usually control capsular tears of the spleen. Lacerations of the splenic substance can be controlled with interlocking absorbable sutures. Major lacerations of the splenic substance can be treated with segmental splenic resection or wrapped in absorbable mesh. Splenic salvage should not be attempted if the patient has protracted hypotension or other severe injuries or if undue delays are encountered in the attempt to repair the spleen. With penetrating injury, damage to adjacent structures, such as the stomach, pancreas, colon, and diaphragm, must be anticipated and investigated.

The nonoperative management of splenic trauma is most attractive if the diagnosis has been made with an abdominal CT scan, the patient is hemodynamically stable, and no other signs of abdominal injury are present. Nonoperative management is successful in such circumstances approximately 90% of the time in adults, and even more often in children. Follow-up CT scans are routinely obtained by some surgeons, but they are probably not necessary if the patient is doing well clinically.¹⁷ In general, nonoperative management should be carried out for the initial 24 to 48 hours in an intensive care unit, and patients should remain hospitalized until the hematocrit remains stable postmobilization. The maximum risk of continued or recurrent bleeding is within the first 48 hours after injury, but there is a decreasing risk of delayed bleeding within the first week postinjury and cases of delayed bleeding even months after injury have been reported.¹⁸

Complications after splenectomy include early transient thrombocytosis, which usually resolves spontaneously within 2 or 3 months. Anticoagulation is neither necessary nor helpful. Delayed hemorrhage, pancreatitis, pancreatic leak, and subphrenic abscess also may occur. Subphrenic abscess is primarily related to associated hollow viscus injuries and is uncommon. Routine “prophylactic” drainage of the subphrenic space should not be done; it is associated with an increased incidence of abscess.

Postsplenectomy Sepsis. Fatal pneumococcal septicemia after splenectomy was first noted in the mid-1950s in children. Postsplenectomy sepsis syndrome is caused by failure to clear one of several encapsulated bacteria in the absence of the spleen. The incidence is inversely related to age and is higher with underlying hematologic disorders such as lymphoma or thalassemia. The incidence of life-threatening sepsis in adult trauma patients is low (<1% to 2%) and the overall clinical significance is not easily defined. Concern about the possibility of postsplenectomy sepsis should not obscure the fact that the initial priority is to arrest hemorrhage and deal with the patient’s immediate life-threatening injuries.

If splenectomy is performed, postoperative follow-up is important.¹⁹ Immunization with the polyvalent pneumococcal vaccine has become the standard of care, and booster immunization is recommended every 3 years. Immunization for *Haemophilus influenzae*, meningococcus, and annually for influenza virus is also recommended. In addition, prophylactic antibiotics, usually oral penicillin, should be given any time the patient is to undergo instrumentation, such as during dental repair or surgery. Postsplenectomy patients should be advised of their increased potential for postsplenectomy sepsis and should carry an identification card to alert health care

workers of this possibility if they develop an infection. Also recommended is that they should be given a several-day supply or prescription for oral antibiotics to be taken at the first sign of infection. All infections should be considered emergencies and treated aggressively with intravenous antibiotics in the hospital.

Liver

The liver, the largest organ in the abdominal cavity, is commonly damaged in blunt and penetrating abdominal trauma as well as in thoracoabdominal injuries. Some series have found that the incidence of liver injuries exceeds that of injuries to the spleen. In any case, the two together account for approximately 75% of all blunt intra-abdominal injuries. Trauma sufficient to lacerate the liver is often associated with injuries to other organs. Spontaneous hemostatic mechanisms are sufficiently effective that approximately 85% or more of patients with liver injuries can be managed nonoperatively.

Patients with significant liver injuries usually have a history of major blunt energy transfer to the right thorax or upper abdomen. Physical findings may be minimal because early bleeding may not cause peritoneal irritation or abdominal distention. Any patient with unexplained persistent or recurrent hypotension after blunt abdominal trauma must be considered at risk for a severe liver injury. DPL or FAST is most helpful in quickly establishing the diagnosis of hemoperitoneum, and if the results are positive, laparotomy is appropriate. In hemodynamically stable patients or patients who respond well to resuscitation, the presence of a liver injury may be suspected based on physical examination or ultrasound. A CT scan with intravenous contrast is indicated to illustrate the magnitude of injury and the presence of associated injuries. The injury should be graded according to the American Association for the Surgery of Trauma (AAST) Liver Trauma Scale. The grade of liver injury, the presence of active extravasation (or “blush”), and a rough estimate of the amount of free fluid present should be noted. However, the decision to proceed to laparotomy is not determined by the grade of injury but should be based on the patient’s clinical response to resuscitation and the presence of other injuries, real or suspected. While earlier recommendations considered a severity grade (AAST grade IV or V) to be an indication for laparotomy, the relatively high mortality of operation and the proven success of nonoperative management do not support this approach.

Liver injuries seen on CT scan in hemodynamically stable patients can be treated nonoperatively as long as the patient is followed closely and the possibility of associated hollow viscus or pancreatic injury is borne in mind.²⁰ Penetrating injuries isolated to the liver can be managed in a similar manner as blunt injuries.²¹ If active contrast extravasation is demonstrated, angiographic embolization should be considered along with the need for operative intervention, although it is not proven whether embolization improves outcomes. However, since active extravasation has been identified in patients without a “blush” on CT, embolization may be considered in all patients with significant bleeding.²² Overall reported success of nonoperative management is greater than 90% in most series. When broken down by grade of injury, the success rate of nonoperative management for injuries grades I through III approaches 95%. In stable patients with ongoing bleeding, angiographic embolization as an adjunct to a protocol of nonoperative management may lower the number of blood transfusions and the number of operations.

Patients with grades III through V liver injuries are generally admitted to the intensive care unit for monitoring of vital signs and serial hematocrit determinations. Patients with grades I and II injuries may be appropriate for a ward bed with

appropriate laboratory and physical examinations. When no evidence of further bleeding is seen, patients can be mobilized and started on a diet. There is no mandated period of bed rest that has been shown to improve success rates of nonoperative management. A repeat CT scan before discharge is not required and normal physical activity is traditionally resumed 3 months postinjury. Liver injuries that do require definitive surgical care present a complex and life-threatening series of problems.

Operative Management. Patients with real or suspected liver injuries who illustrate persistent or recurrent shock require surgical intervention. Injuries vary from simple capsular tears and nonbleeding lacerations, to complex fractures with lobar destruction and extensive parenchymal disruption, to bile duct disruption, to hepatic artery and central venous injuries. The principles of operative management of liver injury are the same regardless of the severity of injury. They involve control of bleeding, removal of devitalized tissue, and establishment of adequate drainage.

Simple lacerations that have stopped bleeding at the time of surgery do not require drainage unless they are deep into the parenchyma, in which case they have an increased probability of postoperative biliary leakage. Subcapsular hematomas are preferably left intact if there is no associated parenchymal injury. Lacerations that continue to bleed despite attempts at local control, including packing, require exploration of the liver wound, and specific vessels and biliary radicals are individually ligated. In the event that bleeding continues, the structures of the porta hepatis should be compressed as a diagnostic maneuver (Pringle maneuver; Fig. 23.4). If the bleeding stops, it is presumed to originate from the portal veins or the hepatic artery. If the bleeding continues, it is presumed to arise principally from the main hepatic veins or inferior vena cava, although this distinction is seldom clear-cut in the operating room. The portal triad can be inter-

mittently occluded to allow improved visualization during placement of sutures as parenchymal vessels are ligated. When selective parenchymal ligation fails, ligation of the hepatic artery is an alternative if the trial Pringle occlusion has had a salutary effect. This is rarely necessary but can occasionally produce dramatic hemostasis. The vessel is occluded as close to the liver injury as possible and after initial efforts at hemostasis have failed.

An alternative for deep lacerations with persistent bleeding is resectional débridement of the involved segment of the liver. This is accomplished by the finger fracture technique, removing devitalized liver or the appropriate portion of the liver. This is required in approximately 5% to 8% of all patients with liver injuries. Subsegmental resection is usually adequate; if segmentectomy or lobectomy is required, a knowledge of the anatomy is imperative so as not to compromise inflow or outflow of the remaining segments. This decision should be made early in the exploration, the blood bank notified, adequate help procured, and exposure obtained.²³ Exposure is best accomplished by complete division of the capsular attachments of the liver. This alternative is associated with operative mortality rates as high as 30% and as such should be avoided unless absolutely necessary.

An additional technique uses an absorbable mesh individually wrapping each lobe of the liver and attaching the mesh to the falciform ligament. This technique is useful, with or without packing, when there are multiple superficial lacerations of the liver with active bleeding and can be used as an alternative to parenchymal débridement.

If blood loss is significant and the patient remains difficult to resuscitate, is hypothermic or acidotic, and has a coagulopathy from massive transfusion, however, an early decision to pack the injury and perform further resuscitation after the abdomen is closed is most appropriate. Packing is done to significantly compress the injured liver with laparotomy pads placed above and below the liver. An absorbable mesh can be

FIGURE 23.4. Pringle maneuver compression of the portal triad structures with a noncrushing vascular clamp for hepatic inflow control. If possible, clamp times should be limited to 15- to 20-minute intervals.

placed over the raw surface and left in place to preserve hemostasis when the packs are removed. For packing to be successful, it should be used early, before coagulopathy has become too severe. A system to evacuate fluid in a closed system should be constructed, or, more commonly, a commercial device is applied (wound vac). Subsequent operative removal of the packs 24 to 72 hours later can be accompanied occasionally by resection and suture ligation as needed. After hemostasis has been achieved, the area may be drained, although this may not diminish the incidence of biloma.

Inability to control bleeding by any of the previously described techniques suggests significant retrohepatic vena caval or adjacent hepatic vein bleeding. Early consideration should be given to complete vascular isolation or the placement of an intracaval shunt. This approach is rarely necessary and should be undertaken only if packing has not controlled hemorrhage from the liver and appropriate expertise is available (Fig. 23.5). To accomplish this, the midline laparotomy incision is extended into the chest, either by a right anterior thoracotomy or, preferably, by a median sternotomy. Infrahepatic (cephalad to the renal veins) and suprahepatic (usually intrapericardial) control of the vena cava is obtained. A shunt or other large conduit (chest tube or endotracheal tube) is then

inserted through a right atrial pursestring suture into the vena cava, and vascular occlusion around the conduit at these sites is obtained. The resultant vascular isolation is always imperfect but may allow better visualization of hepatic vein and vena caval lacerations for direct suture ligation or repair. Total venous occlusion may be equally effective and serves the same general purpose but requires adequate volume loading prior to clamping to preserve cardiac function. The risk of hypotension is significant with either approach, in the former because of significant blood loss during atrial cannulation, and with the latter owing to diminished venous return to the right atrium. Last, in select institutions the availability of venous bypass may be an alternative.

The major complications after liver injury include hemorrhage, respiratory insufficiency, coagulopathy, hypoglycemia, biliary fistula or other bile duct injury, hemobilia, and subdiaphragmatic or intraparenchymal abscess formation. The coagulopathy after liver resection is usually the result of hypothermia and inadequate replacement of blood components. In cases of major liver hemorrhage, it is imperative to work with anesthesia to confirm that adequate fresh frozen plasma is being given along with blood cell replacement. In addition to aggressive component replacement, addition of

FIGURE 23.5. Intracaval shunt used for retrohepatic venous injuries, combined with a Pringle maneuver for isolation of the retrohepatic vena cava for operative repair.

activated factor VII (FVIIa) has anecdotally been lifesaving in select cases. Patients undergoing major hepatic resection or liver destruction need continuous glucose infusion, often 10% dextrose, during the early postoperative period. Hypoalbuminemia is common but does not usually require albumin administration and should be treated simply with aggressive nutritional support. Hyperbilirubinemia is transient and usually peaks in 2 to 3 weeks after major resection. Intrahepatic and subphrenic abscesses can develop, particularly if significant débridement has been necessary. They are diagnosed by clinical evidence of sepsis combined with ultrasound or CT scan and often can be treated with percutaneous drainage. When percutaneous drainage is unsuccessful, drainage can be effected surgically either transperitoneally or posteriorly through the bed of the 12th rib. Biliary fistulas or bilomas usually resolve spontaneously, and major extrahepatic ductal injuries are rare. For the rare biliary leak or fistula that does not close spontaneously, placement of a temporary intrabiliary stent either at the site of injury or, preferably, via the sphincter of Oddi (to decrease intrabiliary pressure) is recommended. A T-tube placed in an otherwise normal common bile duct is inappropriate unless the extrahepatic biliary tree is injured. Hemobilia is a rare complication, occurring with intrahepatic bleeding into the bile ducts, and is best diagnosed with angiography or endoscopy. Angiographic embolization is the treatment of choice.

Stomach

The stomach is vulnerable to penetrating injuries of the upper abdomen and lower chest. The upper abdominal viscera underlie the lower ribs to a level as high as the fourth intercostal space during full expiration. The stomach is injured in 5% to 10% of patients with penetrating abdominal trauma. Hematemesis or blood found on aspiration of the stomach with a nasogastric tube is a finding suggestive of gastric injury. Although many patients with blood in the stomach after penetrating abdominal trauma have a gastric injury, the absence of blood in the gastric aspirate does not rule out such an injury.

At laparotomy, adequate exposure requires mobilization and visualization of the entire stomach. Most of the anterior surface of the stomach can be adequately visualized without extensive mobilization by grasping the edge of the greater curve of the stomach with fingers or Babcock clamps, and the stomach is pulled down and spread. Exposure of the gastroesophageal junction can be difficult if the flare of the costal margin is narrow or if the left lobe of the liver is in the way. Improved exposure is accomplished with extension of the midline incision as high as possible by creating a paraxiphoid extension. The left hepatic lobe is retracted to the right after division of the left triangular ligament. Mobilization of the gastroesophageal junction, encirclement with a tape or drain, and caudal traction into the operative field improves visualization and the performance of any necessary repairs. The posterior wall of the stomach should also be examined for the presence of injuries, particularly if there is an injury on the anterior surface. The posterior stomach is exposed by opening the gastrocolic ligament bluntly to the left of the midline approximately halfway between the stomach and the transverse colon in a relatively avascular area. The lesser sac is entered and the posterior wall of the stomach examined.

Injuries to the stomach are usually easy to repair, primarily in two layers, with an inner layer of 3-0 or 4-0 absorbable sutures followed by an outer layer of 3-0 or 4-0 permanent Lembert sutures. Because of the ample blood supply and large lumen of the stomach in all areas except the gastroesophageal junction and pylorus, there is minimal concern for excessive inversion and luminal compromise. On rare occasions, especially after shotgun wounds, large injuries of the stomach may

require resection. Injuries to the pylorus are rare. If viable tissue is present, it should be closed with a Heineke-Mikulicz pyloroplasty; a concomitant vagotomy is not necessary.

Because of the stomach's position high in the abdomen, penetrating injuries to the stomach are frequently associated with lacerations of the diaphragm. During spontaneous ventilation, there is negative pressure in the pleural cavity and positive pressure in the abdomen, and the resultant pressure gradient causes movement of gastric fluid and particulate matter from the abdomen into the chest. The degree of contamination can be deceptive in the operating room because most occurs before the institution of positive-pressure ventilation and laparotomy. Because even small amounts of contamination can result in an empyema, combined injuries to the stomach and diaphragm require the pleural cavity to be lavaged before closure of the diaphragm. The diaphragmatic laceration should be enlarged enough to allow lavage from the abdomen. The course of the phrenic nerve in the diaphragm should be borne in mind, and enlargement of the diaphragmatic laceration should be done either radially or as peripherally as possible. Occasionally, adequate lavage is difficult because of the amount of pleural contamination or if enlargement of the diaphragmatic laceration cannot be done without risk of de-nervation. In such instances, the patient should be closely followed postoperatively for evidence of the development of an empyema or undergo "prophylactic" video-assisted thorascopic surgery (VATS) to lavage the chest. If empyema develops, it can usually be managed with a VATS approach.²⁴

Blunt injuries to the stomach are rarer than penetrating injuries. The stomach is large, distensible, and mobile. A great deal of force is necessary to cause a blowout of the gastric wall. As a consequence, the mortality rate from associated injuries is high in patients with blunt stomach injuries. Blowout injuries of the stomach also tend to be large and the stomach is more likely to be full at the time of the injury. Thus, blunt trauma injuries are often associated with significant intraperitoneal contamination. Principles of operative exposure and repair are the same as for penetrating injuries.

Duodenum

Penetrating Injuries. Because of the retroperitoneal location of the duodenum close to a number of other viscera and major vascular structures, isolated penetrating injuries to the duodenum are rare. The need for abdominal exploration is usually dictated by associated injuries, and the diagnosis of duodenal injury is usually made in the operating room.²⁵ With blunt trauma, gastrointestinal (GI) contrast CT scans are frequently diagnostic.

Diagnosis and treatment of duodenal injuries in the operating room depend on adequate exposure. Exposure is obtained by incising the lateral peritoneal reflection of the duodenum and mobilizing the duodenum from right to left with a combination of blunt and cautery dissection. This technique is known as the Kocher maneuver, and it can be carried well across the midline to the level of the abdominal aorta, providing exposure of the underlying vena cava and aorta. Entry into the lesser sac by way of the gastrocolic ligament provides exposure of the caudal aspect of the first portion of the duodenum and the medial aspect of the second portion. Exposure of the third and fourth portions of the duodenum, if necessary, is carried out by incising the ligament of Treitz and mobilizing the right colon from right to left so that the right colon and small intestine can be elevated (Cattell maneuver). With this combination of maneuvers, the entire duodenum can be mobilized and exposed for evaluation of any injury. It is critical to identify all injuries at the time of the initial exploration, because overlooked injuries are associated with a significant increase in subsequent morbidity.

TABLE 23.4 **DIAGNOSIS****IMPORTANT ASPECTS TO NOTE FOR DUODENAL INJURIES**

Anatomic relation to the ampulla of Vater
Character of the injury (e.g., a simple laceration vs. destruction of the duodenal wall)
Involved circumference of the duodenum
Associated injuries to the biliary tract, pancreas, or major vascular structures

Grading systems have been devised to characterize duodenal injuries. Although useful for research purposes, the specifics of the grading systems are less important than several simple aspects of the duodenal injury (Table 23.4). Most penetrating injuries to the duodenum are simple lacerations that can be repaired primarily. Such repairs should be done in two layers, with an inner absorbable layer of 3-0 or 4-0 sutures followed by an outer layer of 3-0 or 4-0 permanent Lembert sutures. The closure should be oriented transversely, if possible, to avoid luminal compromise, but transverse orientation is not as critical in the duodenum as it is in the rest of the small intestine. The biliary tract does not require drainage in such cases unless an associated biliary tract injury is present, and the duodenum does not require tube decompression, although both of these maneuvers have been advocated in the past. The periduodenal area should be drained with closed suction drainage.

Injuries that encompass as much as 40% or 50% of the duodenal wall can be successfully closed primarily. Primary repair of injuries larger than this, however, can lead to luminal compromise. If the duodenum has been transected or almost transected, the edges should be débrided and a two-layer primary anastomosis done without tension after mobilization of the duodenum, provided that the transection is not close to the ampulla of Vater. Large injuries of the duodenum can be reinforced with a jejunal patch by bringing up a loop of jejunum and laying it onto the area of injury so that the serosa of the jejunum buttresses the duodenal repair (Fig. 23.6). Alternatively, a Roux-en-Y duodenojejunostomy can drain a large defect internally. If there are severe associated injuries to the pancreas or biliary tract, pancreaticoduodenectomy may be necessary. The morbidity associated with pancreaticoduodenectomy is substantial, and this operation is indicated only if the extent of injury is so great that the necessary resection has, in essence, been done by the injury.

Some duodenal repairs are tenuous. This is a particular problem if there is associated pancreatic injury, raising concern about the digestive action of activated pancreatic enzymes on the repair. Pyloric exclusion defunctionalizes the duodenum and protects the repair from activated pancreatic enzymes until it has had time to heal. A gastrotomy along the greater curvature of the stomach provides access to the pylorus, which is closed with a large running nonabsorbable suture or, alternatively, the pylorus is stapled shut. GI continuity is restored by a gastrojejunostomy (Fig. 23.7). Tube decompression of the duodenum may be performed in extreme duodenal injuries, but the biliary tract does not require decompression except in cases of an associated biliary tract injury. As with all duodenal injuries, the periduodenal area should be externally drained to control postoperative leak as a controlled fistula. With creation of a gastrojejunal anastomosis and no concomitant procedure to decrease gastric acid production, H₂ blockers or proton pump inhibitors should be given in the postoperative period to prevent mar-

FIGURE 23.6. A jejunoileal patch can be used to reinforce repairs of the duodenum. **A:** The duodenum is first repaired. **B:** The retrocolic loop of jejunum is brought up to the area of repair. **C:** The serosa is sewn over the repair.

ginal ulceration. After a number of weeks, the vast majority of patients have reconstituted normal GI continuity. The closure of the pylorus breaks down, regardless of whether the pylorus was closed with absorbable or nonabsorbable suture. As the pylorus reopens, the inherently ulcerogenic gastrojejunostomy gradually closes of its own accord and, thus, does not require a concomitant vagotomy.

Blunt Injuries. Blunt injuries to the duodenum are less common and more difficult to diagnose than penetrating injuries. They can occur in isolation or with pancreatic injury. The need for immediate abdominal exploration is frequently not obvious. Because the duodenum is located in the retroperitoneum, findings on physical examination of the abdomen may be subtle except in cases of associated intra-abdominal injuries. Nonetheless, the physical examination is still one of the best methods for determining the presence of a duodenal injury. This is particularly true if the admission examination is indeterminate, emphasizing the need for serial abdominal examinations.

FIGURE 23.7. Technique of pyloric exclusion for complex duodenal injury.

The serum amylase concentration is helpful in the diagnosis of blunt duodenal injuries; however, the test lacks sensitivity. The duodenum is retroperitoneal, the concentration of amylase in the fluid that leaks is variable, and amylase concentrations often take hours, even days, to increase after injury. Serial determinations of serum amylase are better than a single, isolated determination on admission, but sensitivity is still not good and delays are inherent in serial determinations.

Upper GI series and CT scans with GI contrast are reasonably sensitive for the presence of duodenal injury after blunt trauma. Performance of these tests requires a stable patient without any other obvious indications for abdominal exploration. An advantage of CT over upper GI series is that the rest of the retroperitoneum and peritoneal viscera are also visualized. With either study, extravasation of contrast material from the duodenum constitutes an absolute indication for surgical intervention and repair.

Operative exposure and repair of the duodenum after blunt trauma are the same as for penetrating injuries. Crush injuries are more common after blunt trauma and occasionally require extensive resection, but the injuries can be treated frequently by simple techniques of repair if they are diagnosed in a timely fashion.

Intramural hematoma of the duodenum is a rare injury specific to patients with blunt trauma. It is most common in children after isolated localized force to the upper abdomen (e.g., bicycle handlebar ends). Intramural hematomas occur when the

duodenum is crushed and bleeding occurs in the submucosal or subserosal layers of the duodenum. The duodenum is not perforated. Such hematomas can lead to obstruction of the lumen. If the diagnosis is not made at the time of the initial injury, the obstruction usually takes several days to develop, presumably because of increased accumulation of intramural water as the hemoglobin in the hematoma begins to break down and osmotic forces increase absorption of water. If exploration takes place shortly after injury, intramural hematomas of the duodenum are seen as periduodenal hematomas. All hematomas in the area of the duodenum should be explored to rule out the possibility of perforation. Such exploration includes a Kocher maneuver and mobilization of the duodenum, which in most instances successfully drains subserosal hematomas. Submucosal hematomas, if large and potentially obstructing, may require drainage with a deeper, separate myotomy-type incision. If surgery does not occur shortly after injury, obstructive symptoms become manifest after a number of days. An upper GI series or CT scan should be performed to demonstrate obstruction. The obstruction is usually in the second portion of the duodenum and, in the classic picture, demonstrates a coiled-spring appearance. Debate surrounds the treatment of intramural hematomas of the duodenum if the diagnosis is delayed, but the weight of opinion argues for initial nonoperative treatment. This strategy is usually successful because the hematoma gradually resolves and the obstructive symptoms subside without long-term residual sequelae. If obstructive symptoms persist

beyond 10 to 14 days from the time of diagnosis, abdominal exploration should be undertaken to drain the hematoma, relieve the obstruction, and rule out a missed injury.

Complications. The duodenum is particularly susceptible to leak of repairs because of the presence of intraluminal digestive enzymes. Adequate drainage of the periduodenal area helps to ensure that such leaks are controlled and do not result in an intra-abdominal abscess. Placement of a decompressive duodenal tube to protect duodenal repairs is not necessary. If a duodenal repair breaks down and the duodenum is adequately drained, a duodenal fistula results. In the absence of distal obstruction, foreign body, or persistent infection (the chances of which are minimized by adequate drainage), most of these controlled fistulas ultimately close. They may be slow to resolve, and a wait of several months is advised to allow them to resolve spontaneously. Support with total parenteral nutrition increases the rate of spontaneous closure. If a fistula fails to close after an appropriate waiting period, further surgical intervention is warranted. It consists of reexploration of the abdomen and construction of a defunctionalized Roux-en-Y duodenojejunostomy as a form of internal drainage.

Pancreas

Penetrating Injuries. Penetrating injuries to the pancreas are usually diagnosed in the operating room.²⁶ The pancreas is located in the retroperitoneum, surrounded by a number of other viscera and major vascular structures. As a result, an isolated injury to the pancreas is unusual, and patients with penetrating pancreatic trauma usually have obvious indications for abdominal exploration. Preoperative serum amylase and lipase concentrations are not helpful; they are elevated only in a few patients with penetrating pancreatic injuries.

On abdominal exploration, signs of pancreatic injury include a projectile path that passes near the pancreas, a central hematoma in the upper abdomen, and injuries to the duodenum, vena cava, suprarenal aorta, or mesenteric vessels. In all these instances, the pancreas should be thoroughly explored.

The anterior surface of the pancreas is visualized by entry into the lesser sac of the peritoneal cavity. This is done in the same fashion as outlined previously for exposure of the posterior aspect of the stomach, with division of the gastrocolic ligament in a relatively avascular area to the left of the midline. A thin layer of peritoneum overlies the anterior surface of the pancreas at this point, and complete visualization of the surface sometimes requires incision of this layer.

The tail of the pancreas can be more fully visualized, especially in its posterior aspect, by mobilization of the spleen and the tail of the pancreas as a unit. This is accomplished by incision of any lateral attachments of the spleen to the abdominal wall and mobilization of the spleen with blunt dissection laterally to medially by development of the plane between the anterior surface of the left kidney and the posterior aspect of the spleen. This brings the spleen into the abdominal wound and elevates the posterior aspect of the pancreatic tail for inspection. The posterior aspect of the body of the pancreas is visualized by opening the avascular area at the inferior margin of the body and tail of the pancreas with a combination of sharp and blunt dissection. The pancreas can then be mobilized inferiorly to superiorly. This maneuver is also important to mobilize the pancreas in preparation for distal pancreatic resection.

The posterior aspect of the head of the pancreas can be exposed by an extensive Kocher maneuver. In combination with entry into the lesser sac, this also allows for bimanual palpation of the pancreatic head, with one hand placed on the anterior surface of the pancreas through the hole in the lesser

sac and the other hand placed behind the pancreas in the plane developed by the Kocher maneuver.

In the evaluation of penetrating pancreatic injuries, an important key to operative management is whether a ductal injury is present. Transduodenal intraoperative pancreatography has been recommended. The advantage of this maneuver is that it allows for more definitive determination of the type of operative intervention that should be undertaken. The major disadvantage is that it necessitates entry into the duodenum when there is no associated duodenal injury, which turns simple pancreatic injuries into combined pancreaticoduodenal injuries, with an attendant significant increase in potential postoperative morbidity. A further argument against intraoperative pancreatography is that most injuries to the pancreas can be adequately evaluated and decisions made about appropriate operative treatment without radiographic examination of ductal anatomy. In rare circumstances in which the patient's condition permits and the necessary equipment and expertise are available, the use of intraoperative endoscopic retrograde cholangiopancreatography (ERCP) provides an excellent option.

The operative management of penetrating pancreatic injuries depends on both the location and severity of the injury.²⁷ With respect to location, injuries can be subdivided into those of the head, body, and tail of the pancreas. With respect to severity, injuries can be classified by the degree of parenchymal disruption and the presence or absence of ductal injury.

Contusions of the pancreas, regardless of location, should be either simply observed or drained. The optimal type of drainage is a matter of some debate, and a variety of different drainage methods have been espoused. The type of drain used after pancreatic injury is probably not as important as ensuring that adequate drainage has been effected. If drains are used, they should be left in place for at least 5 to 7 days to ensure that a drain tract develops. Pancreatic fistulas can develop on a delayed basis 3 to 7 days after injury, and if the drains are removed before that time, drainage may be inadequate. The morbidity rate for patients with undrained pancreatic secretions is much greater than for those with drained pancreatic secretions.

The timing of drain removal should be based on both the amount and character of the pancreatic drainage. Drain outputs in excess of 150 to 200 mL/d are suggestive of pancreatic fistulas. Determinations of drain amylase concentration are helpful, but amylase concentrations within a few days of injury, even if very high levels ($>50,000$ IU/L), do not correlate with the development of a pancreatic fistula or other complications. Determinations at 7 days after injury correlate with the persistence of a pancreatic fistula or other pancreatic complication only if the level is higher than 100,000 IU/L, whereas the negative predictive value of a concentration below 100,000 IU/L is poor and does not rule out the presence or subsequent development of a pancreatic complication.

Treatment of major parenchymal disruptions depends on location and the presence of ductal injury. Injuries to the body or tail of the pancreas should be evaluated for possible ductal disruption. It can be difficult to determine definitively whether an injury has occurred to the duct by inspection of the parenchymal injury. If a ductal injury is obvious or likely, the distal pancreas should be resected and the proximal pancreas and pancreatic duct oversewn. Distal resection can include up to 80% of the gland, if necessary. Subsequent endocrine or exocrine insufficiency is rare if the pancreas is normal. If a ductal injury is not present or is unlikely, the pancreas should be drained. Major parenchymal disruptions of the head of the pancreas should be drained, regardless of the presence of ductal disruption, because the morbidity of pancreaticoduodenectomy or attempts at internal drainage is greater than the morbidity of simply draining the area of injury. If a pancreatic fistula develops, drains can control it. If the fistula does not

resolve with time, the pancreas can be drained internally or resected at a later date.

For massive injuries to the duodenum and head of the pancreas, pancreaticoduodenectomy with reconstruction should be reserved for cases in which débridement of devitalized tissue results in a de facto removal of the duodenum and head of the pancreas. Penetrating injuries to the ampulla of Vater also may require formal pancreaticoduodenectomy.

Internal drainage of the pancreas has been suggested as a means of treating ductal injuries without the need for resection of viable and functional pancreatic tissue. Although in theory this approach preserves pancreatic function and minimizes the risk of postoperative pancreatic insufficiency, it has major risks. The pancreaticojejunal anastomosis is susceptible to break down and leak, especially if suboptimal conditions of associated injury and hemodynamic instability exist. The construction of a Roux-en-Y jejunal limb requires the opening of the intestine and the creation of a small bowel anastomosis. If the intestine has not been injured, this procedure increases the amount of contamination associated with the injury as well as the likelihood of postoperative morbidity. For these reasons, most major trauma centers rarely carry out internal drainage procedures in the early postinjury period, relying instead on either resection or drainage. Internal drainage is usually reserved for cases in which persistent pancreatic fistulas or pseudocysts develop late²⁸ and is done on a delayed basis.

Distal pancreatectomy for traumatic injuries should be performed only after the pancreas has been thoroughly mobilized and exposed. In some cases, the pancreas has already been transected, and the site of resection has therefore already been determined for the surgeon. If this is not the case, the pancreas should be transected just proximal to the site of known or presumed ductal injury. If associated splenectomy is planned, elaborate dissection is unnecessary. The splenic artery can be identified near the superior margin of the pancreas and ligated. The splenic vein also can be individually ligated at this point. Commonly, the splenic vein lies behind the body and tail of the pancreas, and its isolation requires more dissection. As an alternative to extensive dissection to isolate the splenic vein behind the pancreas, the vein can be transected along with the pancreatic parenchyma. Individual ligation of the splenic vein stump can be done after the distal pancreas and spleen have been removed. It is helpful first to mobilize the spleen and tail of the pancreas.

The pancreas should be mobilized at the site of transection and can be encircled with a rubber drain. Mobilization and encirclement are best done by an approach to the pancreas along its inferior margin and mobilization inferiorly to superiorly. The pancreas can be divided either distal to a bowel clamp or with a stapler. There are some indications that a sutured closure is less likely to break down and lead to fistula formation than a stapled closure. If a bowel clamp is used, the pancreatic stump should be oversewn with a nonabsorbable running suture. It is recommended that an individual figure-of-eight suture be placed in the cut end of the pancreatic duct. This proves exceedingly difficult in patients with normal pancreatic ductal systems because the duct is small and not easily identified in the cut edge of the pancreatic stump. A pancreatic duct that can be seen easily may indicate preexisting proximal ductal obstruction. In this case, the duct should be individually ligated. If the cut end of the duct is not immediately apparent, time and effort should not be taken to locate and individually ligate it.

It is possible to perform a distal pancreatectomy without a concomitant splenectomy. Splenic salvage involves individual ligation and division of the branches of the splenic artery and vein that supply the body and tail of the pancreas. This adds to operative time and can increase the risk of bleeding, particularly if there is an associated injury to the spleen treated with splenorrhaphy. Splenic salvage should be attempted, therefore,

only in hemodynamically stable patients with minimal or no associated intra-abdominal or extra-abdominal injuries.

Pancreatic injuries can lead to a number of complications, including pancreatic fistulas, pseudocysts, bleeding in the area of the pancreatic bed, and pancreatitis. Pancreatic fistulas after trauma are characterized by persistent drainage of pancreatic enzymes and secretions from the pancreatic injury for a number of weeks after injury. Most of these fistulas close spontaneously, especially if there is no proximal obstruction of the pancreatic ductal system. A trial of total parenteral nutrition may improve the rate and incidence of spontaneous closure. Experience with the use of somatostatin in patients with post-traumatic pancreatic fistulas is limited. Somatostatin given to patients with pancreatic fistulas after elective pancreatic resections seems to decrease the amount of fistula drainage but has not consistently decreased the time to fistula closure and may impact pancreatic healing.

Pseudocysts that develop after pancreatic trauma often resolve on their own or with percutaneous aspiration or drainage. If, after 4 to 6 weeks of observation with serial ultrasound or CT scans, the pseudocyst does not show signs of resolution, it should be drained internally, into either the stomach or a defunctionalized limb of jejunum, depending on its location.

Bleeding in the area of the pancreatic bed is usually an early complication caused by inadequate drainage with resultant autodigestion of the pancreas and surrounding tissue. Bleeding can be avoided by identifying all injuries at the time of exploration and ensuring adequate drainage. If massive bleeding does occur, it should be dealt with through angiographic or operative intervention.

Pancreatitis is another complication of pancreatic injury and is worsened by inadequate drainage of pancreatic secretions. Treatment consists of provision of adequate drainage and supportive care. If the pancreatitis is localized to the distal pancreas and a trial of conservative management fails, distal pancreatectomy should be considered.

Blunt Injuries. The major difference between penetrating and blunt injuries of the pancreas concerns diagnosis. Penetrating injuries are usually discovered on abdominal exploration for associated injuries, but blunt injuries can occur in isolation and the preoperative diagnosis can be difficult. Blunt pancreatic injuries are relatively rare, which increases the difficulty of diagnosis. In one series of pancreatic injuries, delays in diagnosis of blunt injuries ranged up to several days. Making the diagnosis as quickly as possible is important because delays in diagnosis are associated with significantly increased morbidity and mortality.

The body of the pancreas lies directly anterior to the vertebral column and is vulnerable to crush injuries when the anterior abdominal wall is forcibly compressed, as can occur from a seatbelt, steering wheel, or sharp blow to the epigastrium. In such instances, the pancreas may be the only intra-abdominal organ injured.

Physical examination of the abdomen is useful, but because of the retroperitoneal location of the pancreas, the results can be misleadingly benign until a number of hours to days after injury. This emphasizes the importance of serial examinations. In most cases, the abdomen becomes progressively more tender to palpation during the first 24 to 48 hours after injury and the need for abdominal exploration becomes more obvious. The physical examination of the abdomen is much less reliable in young children and in patients with head injuries.

Serum amylase and lipase concentrations drawn on admission have low positive and negative predictive values but are helpful in providing an initial value of these enzymes for comparison with subsequent serial determinations. Serial amylase and lipase concentrations are helpful in monitoring the courses of patients with normal or only mildly elevated admission values, but overreliance on these methods can result in dangerous delays in diagnosis.

Computed tomography scan of the abdomen allows for visualization of the retroperitoneum, including the pancreas. In the case of isolated injury to the pancreas, the sensitivity of the CT scan is at its lowest shortly after injury. Although CT diagnosis of pancreatic injury improves greatly after a number of hours have passed, immediate CT scan of the abdomen sometimes misses pancreatic injuries, particularly if expert interpretation is not available. Serial CT scans, with GI contrast to evaluate the duodenum, should be performed if pancreatic injury is of concern.

Endoscopic retrograde cholangiopancreatography is an attractive diagnostic method for pancreatic injury because it is less invasive than abdominal exploration and also provides information about the status of the ductal system, but there are several practical disadvantages to the technique. Most successful studies using ERCP have involved stable patients studied hours to days after injury at a referral center specifically because of suspicion of a pancreatic injury. These patients are a select group, different from patients who are recently injured. In addition, ERCP is not universally available and, even in large centers, is often unavailable at the odd hours necessary for early diagnosis in acutely injured patients. Many endoscopists are also fearful of inducing an exacerbation of pancreatitis in patients with mild pancreatic injuries lacking ductal involvement. Magnetic resonance cholangiopancreatography (MRCP) is a newer possibility for diagnosis of pancreatic ductal injury in patients with blunt trauma and has also been used as an alternative to ERCP for the investigation of possible postinjury or postoperative complications.²⁹ Experience to date with MRCP is limited, but it has the advantage of being non-invasive and does not cause pancreatitis. Further experience will be necessary to determine whether the false-negative and false-positive rates of MRCP are acceptable in the diagnosis of pancreatic injury.

Basic principles of exposure and operative management of blunt injuries of the pancreas are the same as for penetrating injuries. In many instances of severe injury, the pancreas already has been transected by the trauma, making the pancreatic resection somewhat simpler to carry out. Isolated injuries of the pancreas from blunt trauma also lend themselves to distal pancreatectomy with splenic preservation. As in penetrating injury, splenic salvage should be attempted only in stable patients without associated splenic rupture or severe associated intra-abdominal or extra-abdominal injuries. Complications of blunt pancreatic injury are similar to those outlined for penetrating injuries.

Small Intestine

Penetrating Injuries. Because the small intestine occupies more volume in the peritoneal cavity than any other organ, it is the intra-abdominal viscus most frequently injured by penetrating abdominal trauma. The severity of injury ranges from trivial rents in the bowel serosa or mesentery to massive perforation or devascularization injuries requiring extensive resection.

Diagnosis of small-bowel injury can be made by a number of methods. Physical examination of the abdomen reveals peritoneal signs in many patients with penetrating small-bowel injuries. Patients with gunshot wounds routinely undergo laparotomy. Recently, some have advocated that all patients with penetrating abdominal trauma, including gunshot wounds, who do not exhibit signs of peritonitis or hemodynamic instability should undergo abdominal CT.³⁰ If CT is performed, free air or stranding is an indication for early laparotomy due to the likelihood of bowel injury. However, for abdominal gunshot wounds, most trauma surgeons continue to limit this approach to only very limited tangential or right upper quadrant trajectories.

In stable patients with abdominal stab wounds, local wound exploration may be able to identify a subset of patients without fascial violation who may be discharged from the emergency department. Patients with multiple stab wounds, tangential stab wounds, or indeterminate results of exploration will require further evaluation to identify intraperitoneal injury. Laparotomy for other anterior abdominal stab wounds that violate the abdominal wall fascia should be selective. One method is to use serial abdominal examinations, hematocrits, and leukocyte counts. If the patient shows increasing signs of intraperitoneal injury, abdominal exploration is performed. Another approach is DPL, with a variety of criteria for positivity in patients with anterior abdominal wounds, ranging from 1,000 RBCs/mL of lavage fluid up to the conventional 100,000 RBCs/mL used in patients with blunt trauma. Lastly, CT has been used to determine the track of the wound and potential peritoneal penetration with or without evidence of intestinal or other visceral injury.

Regardless of the approach taken for the preoperative diagnosis of penetrating injuries of the small intestine, the operative approach is the same. The abdomen should be explored through a standard midline incision, and initial attention should be directed toward bleeding from associated injuries or from the small bowel mesentery. Bleeding from the mesentery usually can be controlled with suture ligation or with a rapid running closure of the mesenteric rent. This closure does not need to constitute definitive repair, but, if indicated, it temporarily controls bleeding until definitive treatment is delineated. Care should be taken not to compromise the vascular integrity of the bowel by overzealous suturing of the mesentery.

After bleeding has been controlled, steps to prevent ongoing leakage of intestinal contents from the injured small bowel should be taken. This is done by rapid examination of the small intestine and by application of Babcock or Allis clamps, a temporizing running single-layer closure, or stapled control of the injured areas. Definitive repair or resection should not be done until the entire length of the intestine has been carefully examined because knowledge of the extent of injury is necessary for a logical and rational approach to operative management. It makes no sense, for example, to repair a segment of small intestine only to determine after further exploration that injuries to adjacent segments of the bowel dictate resection of an entire larger segment.

The entire length of the small intestine should be carefully examined, starting at the ligament of Treitz and moving sequentially, proximally to distally, to each successive loop. This should be done in a systematic manner and should include inspection of the small-bowel mesentery by fanning out the mesentery and examining each new loop. When a suspect area is seen along the mesenteric border of the intestine, the mesentery should be cleared away to allow adequate visualization. The small intestine has a good blood supply and easily tolerates this maneuver. Any blood or other debris found on the serosa of the bowel should be wiped away. Sometimes, such debris overlies an otherwise unsuspected area of injury. Compression of the intestine in areas of suspected injury may also demonstrate a leak that would otherwise be missed.

In theory, the number of holes found in the small intestine should add up to an even number because the number of entrance and exit wounds should be identical. This rule is sometimes violated in practice, however, because the intestine is extensively coiled in the peritoneal cavity and tangential wounds of the bowel are common. Rather than focusing on the number of holes in the bowel, attention should be directed to a close inspection of the entire length of the intestine. After all areas of injury have been identified, a decision about repair or resection is made. Areas of massive destruction of the bowel or the mesentery, with associated ischemia, should be treated with resection. If after débridement more than 40% to 50% of the circumference of the wall of the small intestine is missing,

that segment also should be resected. Caution should be exercised in using stapled anastomoses in trauma patients if extensive bowel wall edema is present. With normal intestinal wall thickness, however, stapled anastomoses are particularly useful when time is of the essence and should be constructed in a side-to-side, functional end-to-end fashion.

Knife wounds to the small intestine are usually easy to manage and rarely require extensive débridement or resection. On rare occasions, a large rent in the small bowel mesentery results in enough devascularization to require resection of a segment of intestine.

Minor mesenteric lacerations should be treated with suture ligation of bleeding points and closure of the rent. Major lacerations with devascularization should be treated with resection and primary anastomosis. Small-bowel anastomoses, when properly done and after adequate débridement of devitalized tissue, have an excellent rate of healing even with severe associated injuries, shock, and peritonitis.

Shotgun wounds to the abdomen from close range are often associated with massive tissue destruction, which should be débrided and anastomosis completed as appropriate. Medium- or longer-range shotgun wounds sometimes result in a diffuse pattern of shot injury, creating multiple small perforations of the small intestine. In such instances, the general principles outlined should be followed and obvious areas of injury repaired. It is sometimes impossible to ensure closure of all the numerous areas of perforation, and planned repeat laparotomy may be required to rule out occult injuries.

On rare occasions, injuries to the small intestine occur in patients who are hemodynamically unstable as a result of associated injuries. In such instances, the small intestine can be treated most expeditiously by application of the gastrointestinal anastomosis stapler as necessary to remove the injured areas of bowel as a "damage control" technique. A second operation is planned and definitive anastomosis is deferred with the stapled ends of the intestine returned to the abdomen until the second procedure is performed.

6 Blunt Injuries. Blunt injuries to the small intestine are much less common than penetrating injuries. As with other blunt intra-abdominal injuries, they are more difficult to diagnose because the need for urgent intra-abdominal intervention is not always obvious. Blunt perforations and devascularizations of the small intestine often occur in isolation, either as the only injury or as the only intra-abdominal injury present. This makes early diagnosis even more difficult.³¹

Seatbelts, in particular high-riding lap belts in children, have been implicated in the pathogenesis of blunt injuries of the small intestine. The intestine or mesentery is sheared across the seatbelt to the point of rupture or disruption of its mesentery, resulting in either perforation or devascularization. Because of the severe degree of force necessary to produce a blunt intestinal injury, there is a frequent association with transverse fractures of a lumbar vertebral body (Chance fracture), caused by flexion or distraction over the seatbelt.

Abdominal examination is usually positive shortly after injury, but initial findings in some cases can be subtle, resulting in delays in diagnosis. The presence of a Chance fracture and a lower abdominal lap belt transverse contusion warrants a high index of suspicion and a thorough search for intestinal injury. If head injury or intoxication makes physical examination of the abdomen unreliable, the initial CT scan should be closely scrutinized for clues of intestinal injury. CT, particularly if done early after injury, is not completely reliable in ruling out blunt intestinal injury. The injury itself may not be obvious, and it is important to look for findings that may indicate blunt abdominal injury. This includes free fluid without solid organ injury, focal bowel wall thickening, free air, or extravasation of oral contrast (if used). Small amounts of intraperitoneal fluid should not be ignored. If the CT is scruti-

nized for all of these findings, then the sensitivity of CT is actually quite high. If these findings are present, the CT may be repeated in 4 to 6 hours to evaluate for progression of the injury.³² A follow-up DPL can also be valuable if there are concerns about radiation or contrast. If the patient is fully evaluable and does not have any signs or symptoms of injury, these studies may be obviated for careful serial exams. If abdominal pain or tenderness is present, a follow-up study is prudent. Optimally, the intestinal injury should be identified within 6 to 8 hours. Intervention greater than 12 to 24 hours will have a substantial increase in morbidity and mortality. Blunt injuries to the small intestine are most common in either the proximal jejunum or the distal ileum, probably because the intestine is fixed at these two points and more vulnerable to shear and stretch injuries. Multiple injuries to the small intestine from blunt trauma occur in approximately 25% of cases. Second or even third areas of injury should be carefully sought if a blunt intestinal injury is discovered on abdominal exploration.

After the suspicion of blunt intestinal or other intra-abdominal injury has been raised and the decision to explore the abdomen has been made, the basic principles of abdominal exploration and operative management of blunt small-bowel injuries are the same as for penetrating injuries. Because of the nature of the mechanism of injury, the perforations are usually amenable to primary repair. Mesenteric rents that cause devascularization and require resection are relatively more common after blunt injury than after penetrating injury. The radiologic and physical findings associated with these types of injuries are initially more subtle, but become obvious after the devascularized bowel perforates. This may lead to a delay in laparotomy and definitive control.

Colon and Rectum

Most injuries to the colon and rectum are the result of penetrating or perforating trauma. Blunt trauma accounts for only approximately 5% of colonic injuries. Rectal injuries can occur in association with pelvic fractures and the possibility of rectal injury must be considered in any patient with a significant pelvic fracture, in addition to evaluation of other pelvic viscera such as the bladder, distal ureters, uterus, and vagina.

Signs and symptoms of peritonitis result from injury to the colon and rectum but are not specific. Injury to the extraperitoneal rectum is particularly difficult to recognize because peritonitis does not result. Conventional laboratory studies usually are not helpful. Plain radiographs may show free air in the peritoneal cavity, but this finding is relatively uncommon; when it is not present, the patient cannot be assumed to be free of bowel perforation. DPL may be of value if intraperitoneal colonic injury is present, yielding lavage fluid with blood, bacteria, or fecal material. If the injury is confined to the extraperitoneal colon and rectum, however, DPL is of no value. Extraperitoneal colonic or rectal injury is extremely difficult to diagnose. The possibility of rectal injury must be considered in any patient with penetrating trauma to the lower abdomen or buttocks. CT scan may be useful in delineating the trajectory of a bullet, and further workup can be selectively applied based on the proximity of the trajectory to the extraperitoneal rectum.³³ Digital rectal examination is essential. The presence of blood on examination is strong evidence for colon or rectal injury, and proctoscopic and sigmoidoscopic examinations should be performed. As blood may be the only finding indicating an injury, it is essential that the operating surgeon perform the sigmoidoscopy first so that less experienced endoscopists do not contaminate the field with procedure-induced blood. Water-soluble contrast studies also may be useful, but direct bowel examination usually is preferable. Approximately 95% of colon injuries are caused by gunshot, shotgun, or stab wounds, and, whenever the possibility of colonic injury is entertained, broad-spectrum intravenous

TABLE 23.5 MANAGEMENT**PRINCIPLES OF OPERATIVE MANAGEMENT OF COLON AND RECTAL INJURIES**

Placement of the patient in the lithotomy position to provide simultaneous exposure of both the perineum and abdomen
Wide débridement of all dead and devitalized tissue
A totally defunctioning colostomy (simple loop colostomy may be inadequate)
Rectal wall closure, if the injury is easily accessible
Retrorectal drainage, primarily in severe injuries
Distal rectal stump washout if easily feasible
Broad-spectrum intravenous antibiotics, nutritional support, and serial débridement

prophylactic antibiotics should be started immediately and continued postoperatively using a standard protocol limiting their use to no more than 2 to 3 days.

The longstanding controversy between primary repair of low-risk colonic injuries and repair or resection with exteriorization has been largely resolved.³⁴ Primary repair is preferred after additional risk factors that increase the incidence of complications have been excluded, such as preoperative hypotension, intraperitoneal hemorrhage exceeding 1 L, more than two additional injured organs (hepatic, pancreatic, and splenic injuries have the highest morbidity rates), gross fecal spillage, or an elapsed time since injury of more than 6 hours. Many patients with penetrating colon injuries, however, can be treated with primary closure even in the presence of these risk factors. Resection and colostomy are an overly conservative approach, and recent series indicate that primary repair may be safe even in the presence of some risk factors.³⁵ Exteriorization of the repaired segment has also been advocated, but the success of this technique is low and has little benefit over diverting colostomy alone. Overall primary repair is indicated for most colon wounds, but each surgeon must decide in the context of the individual patient's risks. Postoperative complications include abscess formation, anastomotic leak, peristomal hernia, and the morbidity and mortality associated with colostomy closure.

The morbidity and mortality from rectal injuries is primarily a result of inadequate initial therapy and the complications associated with delayed sepsis. Rectal injury must be suspected in any penetrating injury that enters the buttocks or tracks into the true pelvis, or if a pelvic fracture produces a ring disruption or large displaced bone fragments. Sigmoidoscopic examination is essential. The principles of operative management of colon and rectal injuries are outlined in Table 23.5.

Complete rectal destruction is a rare injury for which primary abdominoperineal resection with packing may be necessary. If done, the packing should be removed operatively in approximately 48 hours. Complications of rectal injuries include pelvic abscesses, urinary or rectal fistulas, rectal incontinence and stricture, urinary incontinence, and loss of sexual function.

Retroperitoneal Hematoma

The optimal management of retroperitoneal hematoma depends on a number of factors, including its cause, its location, and the presence of associated injuries. The retroperitoneum can be divided into anatomic zones for purposes of decision making (Fig. 23.8 and Table 23.6). Retroperitoneal

**FIGURE 23.8.** Zones of the retroperitoneum.

hematomas in zone 1, regardless of cause or size, are formally explored with inspection of each of the relevant structures. This is required because of the high incidence of associated major vascular, pancreatic, or duodenal injuries and the high morbidity and mortality rates if these are overlooked.

Zone 2 hematomas caused by penetrating injuries are routinely explored if encountered in the operating room. Whether proximal control of the renal pedicle should be obtained before exploration of a perinephric hematoma is controversial. In cases of severe ongoing hemorrhage, time should not be taken to obtain proximal control, and the kidney should be mobilized directly. If time and the degree of hemorrhage permit, however, it is acceptable to obtain vascular control before mobilization of the kidney. Zone 2 hematomas caused by blunt trauma can be left alone if they are not expanding.

TABLE 23.6**ZONES OF THE PERITONEUM**

■ ZONE	■ LOCATION	■ ASSOCIATED INJURIES
1	Central retroperitoneum	Pancreaticoduodenal injuries or major abdominal vascular injury
2	Flank or perinephric area	Injuries to the genitourinary tract or to the colon (i.e., with penetrating trauma)
3	Pelvis	Pelvic fractures

Zone 3 retroperitoneal hematomas in patients with penetrating injuries should be explored to exclude major vascular injuries. Bleeding from iliac vessels can be challenging and have a significant mortality. Venous control with direct pressure and dissection allows exposure for diagnosis, ligation, or repair. Arterial injuries are controlled proximally and occasionally require distal control below the inguinal ligament due to extensive collateral blood flow. Patients with zone 3 hematomas secondary to blunt trauma usually have associated pelvic fractures. If found at laparotomy, exploration of the hematoma can be hazardous and difficult to control and is avoided. There is often combined extensive injury to the rich presacral venous plexus and arterial circulation. Incision of the peritoneum releases the tamponade, and dissection within the hematoma can produce catastrophic bleeding. Discrete bleeding points rarely can be identified. Exploration of these hematomas is associated with an increased requirement for transfusion and a higher mortality rate. Pelvic packing is useful for substantial hematomas, with a return to the operating room in 24 to 72 hours for pack removal. Zone 3 hematomas found on CT or clinically suspected that are associated with hemodynamic instability are best managed with angiographic embolization and/or, less commonly, external pelvic fixation. Recently, extraperitoneal packing through a Pfannenstiel incision has been described as an exigent option, particularly if angiography is not available.³⁶

CHAPTER 24 ■ GENITOURINARY TRAUMA

THOMAS G. SMITH III AND HUNTER WESSELLS

KEY POINTS

- 1 Upper urinary tract injury is an infrequent result of trauma, and the majority of injuries result from blunt mechanisms.
- 2 Risk of renal injury requiring further evaluation is indicated by gross hematuria or microscopic hematuria with an episode of hypotension in adults or significant microscopic hematuria in children.
- 3 Most renal injuries are managed nonoperatively, with indications for exploration being symptomatic renal hemorrhage causing hypotension, expanding or pulsatile retroperitoneal hematoma at laparotomy, and grade V injury.
- 4 Ureteral injuries due to external violence are rare and require a heightened index of suspicion due to lack of consistent physical findings.
- 5 Injuries to the bladder require prompt diagnosis, with intraperitoneal injuries necessitating surgical repair.
- 6 Initial management of urethral injuries varies based on location (anterior vs. posterior) and severity, the most severe requiring urinary diversion with a suprapubic tube.
- 7 Primary open reconstruction of posterior urethral injuries secondary to pelvic fracture is discouraged, and primary endoscopic realignment should be undertaken only by a surgeon experienced with this technique.

The incidence of trauma is rising, and the World Health Organization estimates that without change or intervention, road traffic injuries will be the sixth leading cause of death by the year 2020 worldwide. Internal injuries were the fifth leading nonfatal injury noted, while pelvic fracture was the 12th, accounting for 6.3% and 2.6%, respectively, of all traffic injuries worldwide.¹ In the United States, abdominal organ injuries resulted in 6.3% of total injuries, while pelvic injuries resulted in 4.5%.² Based on current U.S. population data, approximately 15,000 persons will sustain renal injuries requiring hospital evaluation annually. Urethral and bladder injuries occur in approximately 10% to 15% of pelvic fractures, and the number of pelvic fractures in 2007 was greater than 67,000. Thus, in the United States, the number of bladder and urethral injuries sustained in 2007 can be estimated between 5,000 and 10,000 persons. While injuries to the genitourinary system as a whole are rarely life-threatening, the potential morbidity is quite high and the resultant effects on quality of life marked. Although few prospective randomized studies examining genitourinary trauma management exist, genitourinary injuries have reproducible clinical presentations, and imaging modalities have improved our ability to identify and treat these injuries. We review the fundamental principles guiding the evaluation and treatment of genitourinary trauma including the American Association for the Surgery of Trauma (AAST) organ injury scale (Table 24.1) and the Société Internationale D'Urologie (SIU) guidelines for management.

UPPER URINARY TRACT INJURY

Kidney

- 1 Injury to the upper urinary tract (kidney, ureter) is rare following trauma, with an incidence of renal injury of 4.89 per 100,000 persons.³ Injury occurs in 1.14% to 3.25% of trauma patients, predominantly males aged 20 to 30 years.^{4,5} Injuries are categorized as either blunt (81% to 95%) or penetrating (5% to 19%) trauma.⁶ The majority of blunt traumatic injury is the result of motor vehicle collision (47% to 66%), with fall second (13% to 16%) and motor vehicle–pedestrian collision

third (4% to 7%) in two large population-based studies.^{3,7} Penetrating injury predominantly is due to firearms (15% to 18%) and stab wounds (6% to 10%).⁸

Anatomically, the kidneys lie in the retroperitoneum, protected by the ribcage, retroperitoneal fat, perirenal fat within Gerota capsule, and overlying viscera (right: liver, colon, duodenum, adrenal; left: spleen, colon, adrenal, pancreas). The collecting system begins within the kidney, forms the renal pelvis, and concentrically narrows at the ureteropelvic junction (UPJ) to become the ureter. The ureter then traverses the retroperitoneum inferiorly, protected by retroperitoneal fat and the psoas muscle. After crossing over the common iliac vessels, the ureter descends into the pelvis, coursing caudad to the base of the bladder and entering the trigone obliquely at the ureterovesical junction (UVJ).

Recognizing the factors that predispose to upper urinary tract injury facilitates early diagnosis and management, which is associated with improved outcomes (Algorithm 24.1). Hematuria is the most sensitive clinical sign of renal injury, yet the degree does not predict injury severity. Our Harborview Medical Center guidelines for imaging of suspected blunt renal injury are consistent with the recent SIU Consensus Panel: in adults, gross hematuria or microhematuria (greater than 3 red blood cells [RBC]/high-powered field [hpf]) with a period of hypotension (systolic blood pressure [SBP] <90 mm Hg), and in children (younger than 15 years), greater than 50 RBC/hpf.⁶ Contrast-enhanced computed tomography (CT) is the preferred imaging modality in stable patients, and the widespread use of CT provides accurate staging of upper urinary tract injuries using the AAST scale (Fig. 24.1).^{6,9} The scan consists of early venous phase contrast-enhanced images detecting vascular blush, parenchymal integrity, retroperitoneal hematoma, and renal parenchymal perfusion. Delayed (10 minutes) imaging is essential for identifying collecting system injury (urinary extravasation, hydronephrosis) and ureteral continuity to the bladder. Conventional intravenous urography (IVU) with tomography, though inferior to CT, can be used for staging when CT is not available.^{10,11} The ability of a single-shot urography to stage injuries is limited to an operative setting and should not be used for clinical staging. Focused abdominal ultrasound for trauma (FAST) remains investigational for

TABLE 24.1

CLASSIFICATION

AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA (AAST) ORGAN INJURY SCALES FOR URINARY TRACT

■ INJURED STRUCTURE	■ AAST GRADE	■ CHARACTERISTICS OF INJURY
Kidney ^a	I	Contusion with microscopic or gross hematuria, urologic studies normal; nonexpanding subcapsular hematoma without parenchymal laceration
	II	Nonexpanding perirenal hematoma confined to renal retroperitoneum; laceration <1.0 cm parenchymal depth of renal cortex without urinary extravasation
	III	Laceration >1.0 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
	IV	Parenchymal laceration extending through renal cortex, medulla, and collecting system with urinary extravasation; injury to main renal artery or vein with contained hemorrhage
	V	Completely shattered kidney; avulsion of renal hilum that devascularizes kidney
Ureter ^a	I	Contusion or hematoma without devascularization
	II	<50% transection
	III	50% transection
	IV	Complete transection with <2 cm devascularization
	V	Avulsion with >2 cm devascularization
Bladder ^b	I	Contusion, intramural hematoma; partial-thickness laceration
	II	Extraperitoneal bladder wall laceration <2 cm
	III	Extraperitoneal bladder wall laceration >2 cm or intraperitoneal bladder wall laceration <2 cm
	IV	Intraperitoneal bladder wall laceration >2 cm
	V	Intraperitoneal or extraperitoneal bladder wall laceration extending into bladder neck or ureteral orifice (trigone)
Urethra	I	Contusion with blood at urethral meatus and normal urethrography
	II	Stretch injury with elongation of urethra, but without extravasation of urethrography contrast material
	III	Partial disruption with extravasation of urethrography contrast material at injury site with visualization in the bladder
	IV	Complete disruption with <2 cm urethral separation and extravasation of urethrography contrast material at injury site, without visualization in the bladder
	V	Complete transection with 2 cm urethral separation or extension into the prostate or vagina

^aAdvance one grade for bilateral injuries, up to grade III.

^bAdvance one grade for multiple injuries, up to grade III.

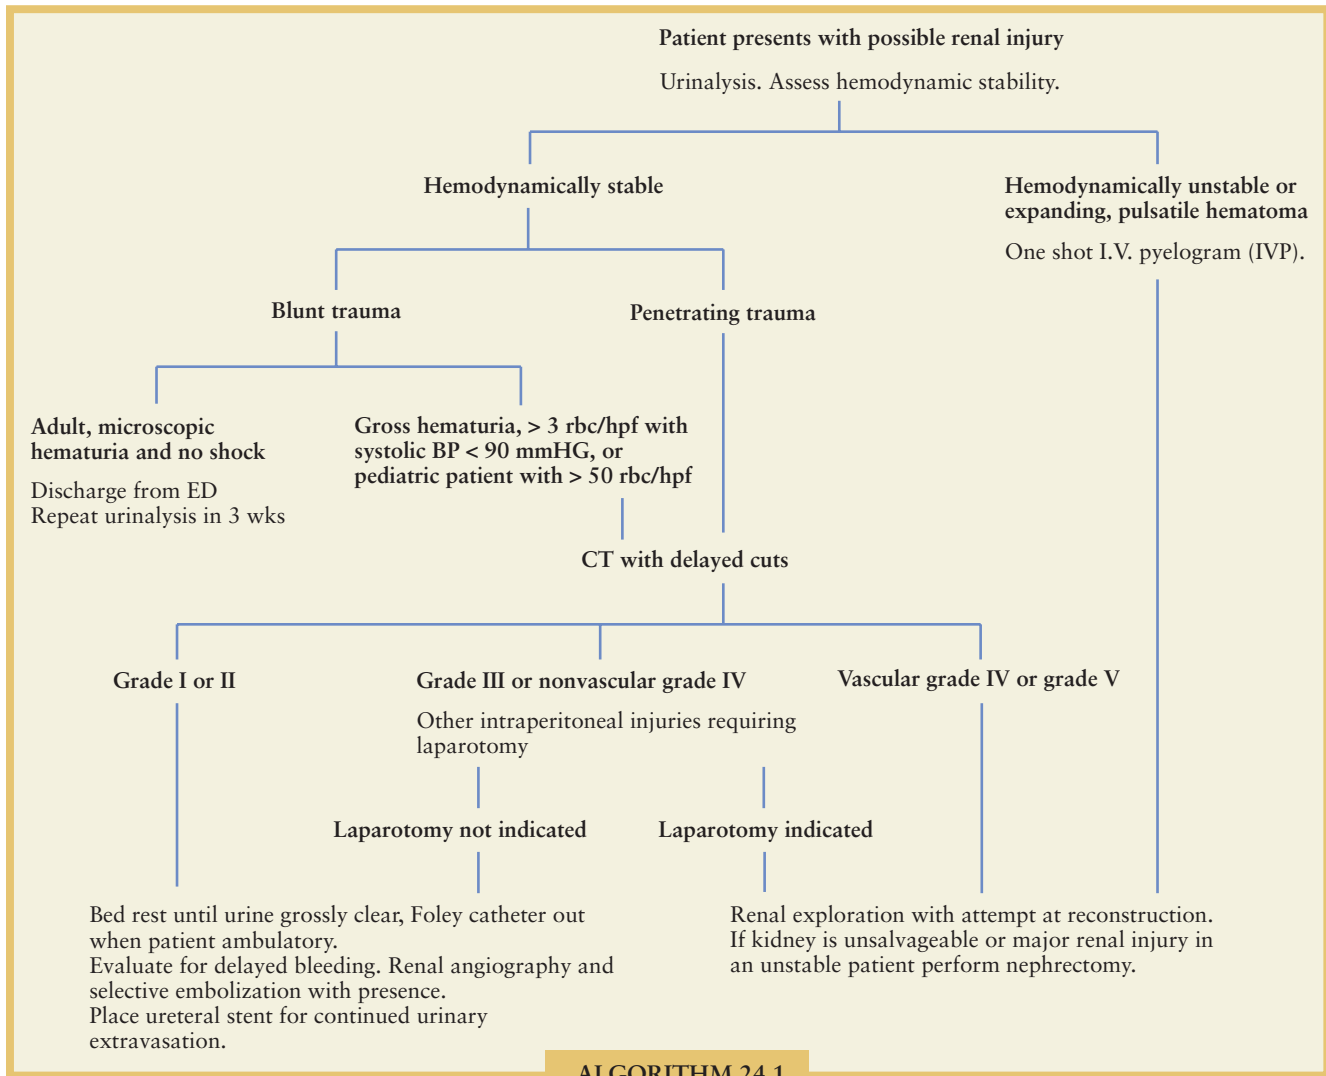

Adapted from Wessells H. Injuries to the urogenital tract. In Souba WW, Fink MP, Jurkovich GJ, et al., eds. *ACS Surgery*, 6th ed. New York: WebMD; 2002;10:3.

detecting urologic injury and is inferior to CT.^{12,13} Renal arterial angiography is rarely used diagnostically but therapeutically is indicated to treat isolated, symptomatic (early or late) renal bleeding, arteriovenous fistula, or pseudoaneurysm using embolization.¹⁴

- 3 Most injuries can be managed nonoperatively.^{3,15} Grade I and II injuries often require no further management. The bulk of blunt grade III and nonvascular grade IV injuries can be managed expectantly. Select penetrating injuries in hemodynamically stable patients can be managed on observation protocols as well.¹⁶ The absolute indications for renal exploration include hemodynamic instability secondary to renal hemorrhage, expanding or pulsatile retroperitoneal hematoma at laparotomy, and pedicle avulsion. Furthermore, in patients undergoing laparotomy for concomitant intraperitoneal injuries, exploration should be considered for deep grade III or IV lacerations, with or without devitalized kidney fragments, because the incidence of complications from nonoperative management can potentially be reduced.^{10,17} If renal exploration is contemplated or necessary, demonstration of contralateral renal function is important in the event ipsilateral nephrectomy is performed. In patients in whom immediate laparotomy is performed without preoperative imaging,

an intraoperative single-shot urogram (kidneys, ureter, bladder [KUB] 10 minutes following intravenous injection of 2 mL/kg contrast) can provide this limited information.^{11,18} Failure to demonstrate contrast excretion from the contralateral kidney may indicate a solitary kidney, hilar injury, hypoperfusion, or global renal insufficiency secondary to chronic renal disease. Exploration of a solitary kidney should be performed only when absolute indications exist.

The kidney and upper urinary tract are accessed through a midline abdominal incision. Using the inferior mesenteric vein (IMV) as a landmark, a posterior peritoneal window is created medial to the IMV overlying the aorta, which allows access, dissection, and control of the proximal renal vasculature.^{19,20} Alternatively, mobilization of the right or left colon provides access to the renal hilum and direct rapid mobilization of the kidney.²¹ If this method is employed, manual compression of the renal pedicle followed by vascular clamping may be required. Cooling is not routinely employed due to time constraints and potential for worsening hypothermia. After obtaining control of the renal artery and vein with vessel loops, the retroperitoneum is entered by mobilizing the colon (if not previously performed) and exposing the Gerota fascia, which is then opened, allowing one to dissect away the perinephric fat.

ALGORITHM 24.1. Evaluation and management of suspected kidney injury.

The capsule of the kidney is routinely left intact for closure following renal reconstruction. During renal exploration, sharp débridement, hemostasis, collecting system repair, and pledgeted, bolstered closure of the renal capsule using absorbable suture is performed. A perinephric suction drain is placed away from the repair in the retroperitoneum and removed when drainage subsides, usually less than 50 mL/d. If concern exists regarding the nature of the drainage, an aliquot of fluid can be sent for creatinine concentration to evaluate for the presence of urine.

In the case of renal artery thrombosis, surgical revascularization is rarely helpful because of the time delay from injury to revascularization. Intervention is commonly limited to patients with solitary kidney or bilateral injuries.^{22,23} An emerging therapy is vascular stent placement through the injury or thrombus; however, most series are limited and results mixed.²⁴ Venous injuries often result in massive bleeding and may require nephrectomy. Isolated proximal left renal vein injuries can potentially be managed by controlling and oversewing the caval stump because left renal vein collateral drainage is present via the gonadal, adrenal, and lumbar veins. Right renal venous injury requires repair, if feasible, or nephrectomy due to lack of collateral circulation.

Frequent clinical monitoring for ongoing bleeding is essential.⁶ Postoperative complications of ileus, urinoma, atelectasis, and infection can occur. Secondary bleeding of nonoperatively

managed and explored kidneys should be managed angiographically, because nephrectomy is likely with exploration. Late complications are uncommon and include renin-mediated hypertension from chronic renal ischemia, arteriovenous malformations, and segmental arteriolar pseudoaneurysm.

Ureter

- 4 Ureteral injuries are rare (1%), with fewer than 10 (due to external causes) presenting annually in busy trauma centers.²⁵ As these injuries often present without clear signs or symptoms, many are missed at the initial assessment and delayed diagnosis is common (Algorithm 24.2).²⁶ The most common source of injury to the ureter is iatrogenic during hysterectomy. These injuries occur with ligation of the infundibulopelvic ligament where the ureter crosses the uterine artery.²⁷ In the adult population, penetrating injuries, gunshot wounds followed distantly by stab wounds, are the most frequent source of injury associated with external violence.^{28,29} A high degree of suspicion should accompany the evaluation of penetrating wounds and injury should be suspected when organs anatomically related to the ureter sustain injury: iliac vessels, bladder, sigmoid colon, and lumbar spine or transverse processes. Significant deceleration and hyperextension mechanisms can result in blunt avulsion as well. In children, the

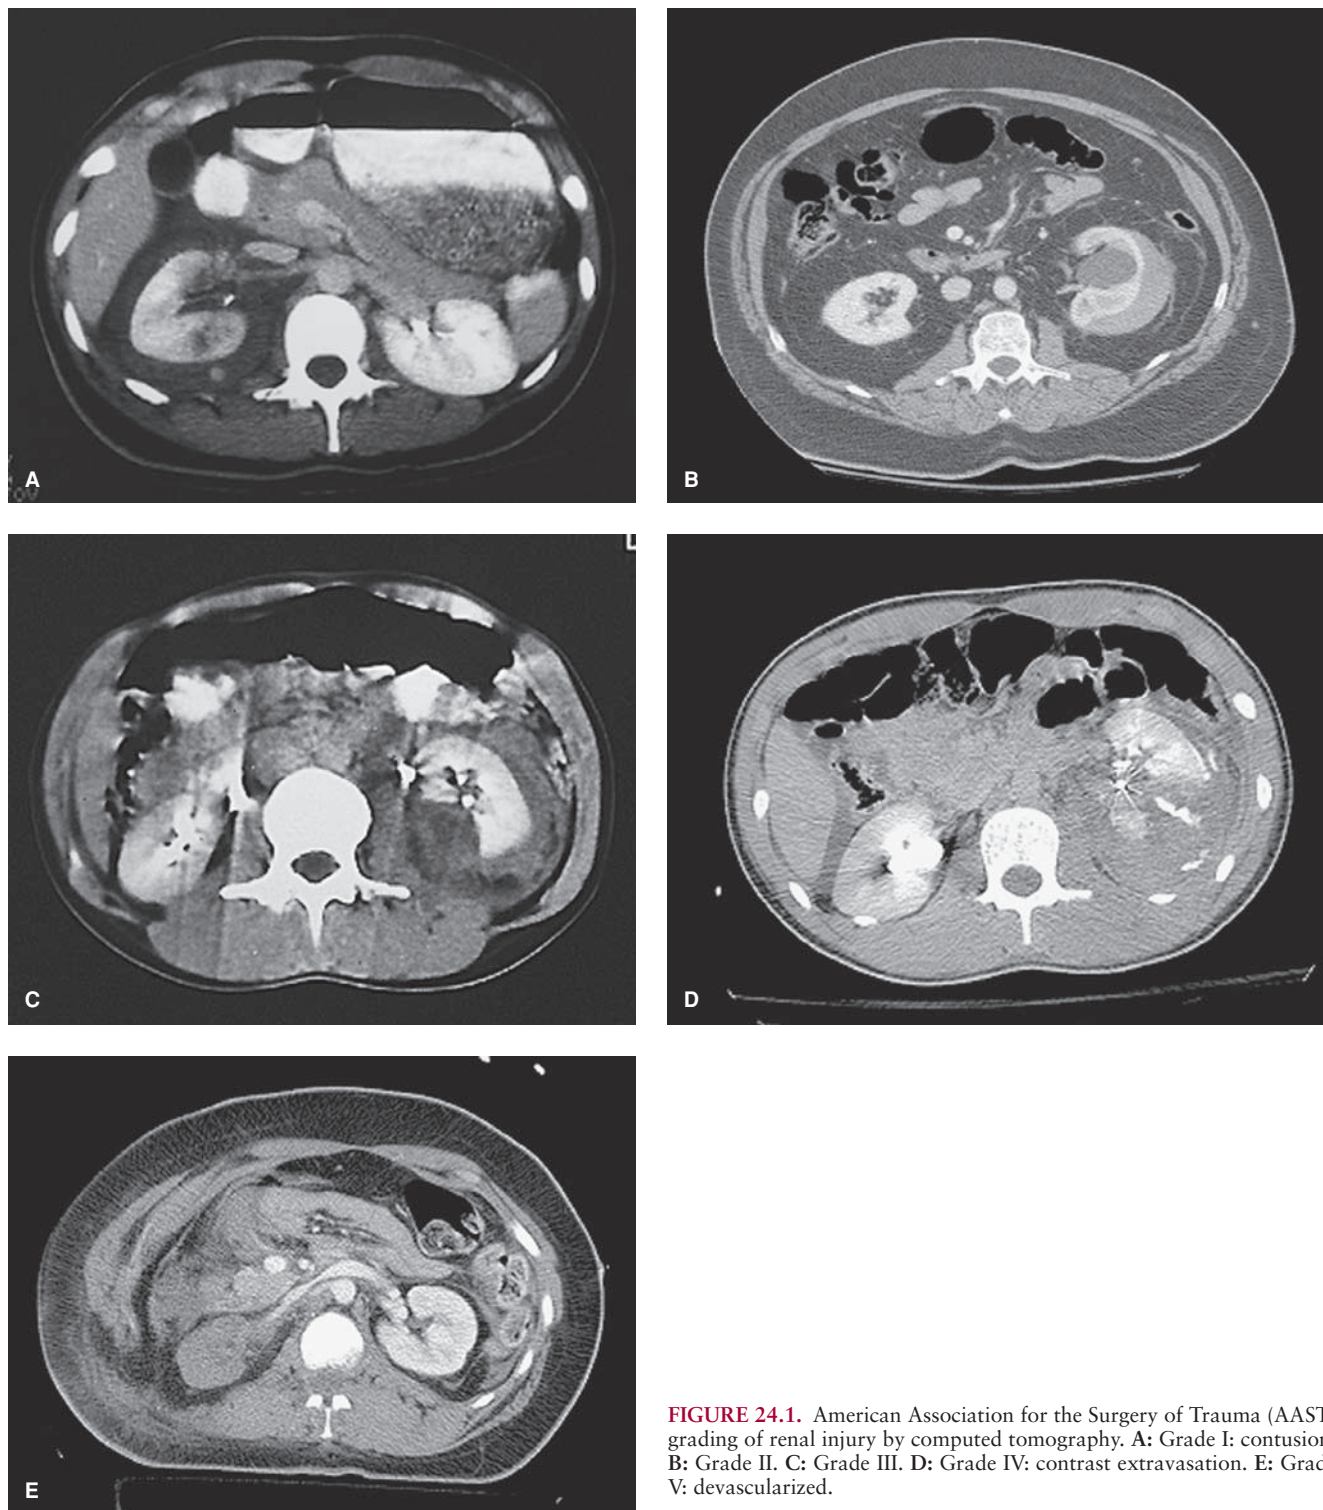

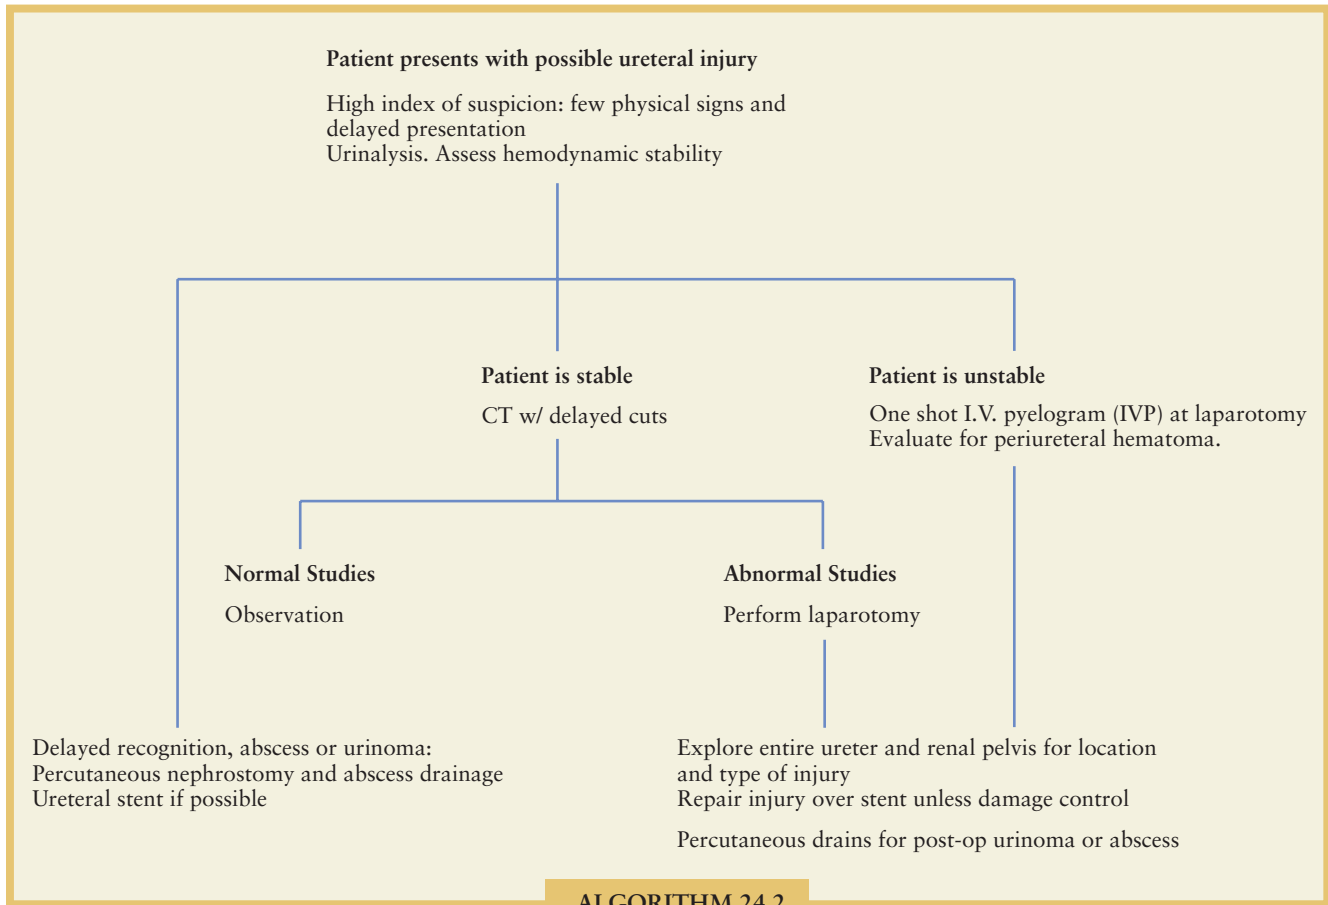

FIGURE 24.1. American Association for the Surgery of Trauma (AAST) grading of renal injury by computed tomography. A: Grade I: contusion. B: Grade II. C: Grade III. D: Grade IV: contrast extravasation. E: Grade V: devascularized.

injury occurs at the UPJ, resulting in avulsion of the ureter due to increased hyperextensibility of the spine.

Anatomically, the ureters begin posterior to the renal hilum at the UPJ. Subsequently, they course inferiorly through the retroperitoneum, along the anterior aspect of the psoas muscle. Upon entering the pelvis, the gonadal vessels run over the ureters, which subsequently traverse over the iliac vessels. Finally, the ureters continue caudally and enter the inferior aspect of the bladder obliquely. The blood supply is segmental and arises from the adjacent anatomic structures within the retroperitoneum and pelvis (proximal-lateral, mid-/true pelvis-medial, and inferior-posterolateral).

Often, patients with penetrating ureteral injuries undergo surgical exploration for associated injuries, allowing the ureter to be inspected directly.^{30,31} Definitive reconstruction should be performed only if the patient is stable. When the defect is too long for primary repair or patients are hemodynamically unstable, damage control techniques for urinary diversion include débridement, drainage of the bladder and retroperitoneum, cutaneous ureterostomy diversion with a feeding tube, or ligation of the ureter with percutaneous nephrostomy tube placement. Complete débridement precedes ureter reconstruction, and the level and length of ureter dictate the type of repair (Fig. 24.2). UPJ disruptions require formal reconstruction by reanastomosis

ALGORITHM 24.2. Evaluation and management of suspected ureteral injury.

FIGURE 24.2. Ureteral reconstruction by location of injury.

or ureteropyelostomy. For ureteral injuries occurring in the proximal to midureter without associated renal injury, simple mobilization of the colon without hilar control can be used to gain access to the ureters. Short midureteric injuries are repaired by spatulated end-to-end anastomosis and low pelvic ureteric injuries are repaired by ureteroneocystostomy (Fig. 24.3). A nonrefluxing anastomosis is preferred in children, while a refluxing implant is acceptable in adults.

Patients presenting with a delay in diagnosis have symptoms of fever, flank pain, fullness, tenderness, atelectasis, or oliguria as a result of urinoma, hematoma, or abscess.³² Operative intervention at the time of delayed diagnosis can result in nephrectomy. Therefore, management includes nephrostomy tube placement, percutaneous urinoma drainage, and Foley catheter insertion. Stent placement across an injury is delayed for 1 to 2 weeks and reconstruction is planned at 3 to 6 months to allow for resolution of periureteral inflammation. Long-term complications of unrecognized ureteral injury include fistula, fluid collections, ureteral stricture, and obstructive uropathy.

All individuals who have sustained injury to the upper urinary tract require follow-up, consisting of imaging in the form of radionuclide scanning or IVU at 3 and 12 months to evaluate for hydronephrosis and document parenchymal function.³³ Interval ultrasound to evaluate for urinoma or abscess is an acceptable imaging modality and limits radiation exposure.

LOWER URINARY TRACT INJURY

Bladder

- 5** Injury to the bladder is rare, occurring in 1% to 2% of trauma patients most commonly secondary to blunt trauma.³⁴

FIGURE 24.3. Techniques of ureteral repair. **A:** End-to-end ureteroureterostomy. **B:** Vesico-psoas hitch reconstruction with reimplantation performed by suturing of the bladder to psoas tendon after mobilization of both obliterated umbilical, plus or minus contralateral superior vesical, pedicles, avoiding the genitofemoral nerve. **C:** Boari flap performed using a tubularized bladder flap based on the ipsilateral superior vesical artery. **D:** Transureteroureterostomy (TUU). For all repairs the principles include tension-free, watertight, stented, spatulated, mucosa-to-mucosa anastomosis using absorbable suture with drain placement.

Penetrating trauma accounts for 0% to 45% of bladder trauma and blunt trauma accounts for the remainder.³⁵ Pelvic fractures are frequently associated with lower urinary tract injuries. An associated pelvic fracture is present in nearly 90% of cases, though only 5% to 10% of pelvic fractures result in bladder injury.³⁶ In pelvic fracture two mechanisms predominate as causes of bladder injury, usually resulting in extraperitoneal rupture. The first involves shearing forces at deceleration

resulting in injury at the fixed sites of pelvic fascial attachment. The second mechanism involves direct injury from pelvic bone fragments causing laceration of the bladder. Intraperitoneal blunt injury is due to rapid deceleration creating a rapid rise in intravesical pressure, resulting in a “burst”-type injury. Extraperitoneal injuries account for 54% to 55% of bladder injuries, intraperitoneal injuries for 38% to 40%, and combined injuries for 5% to 8%.³⁷ In the pediatric population, a

larger proportion of injuries are intraperitoneal because of the relative intra-abdominal location of the bladder. However, the overall incidence is lower. The incidence of pelvic fracture is also lower in children, but, in contradistinction to adults, bladder neck injuries are more common in boys with a pelvic crush injury rather than urethral injuries as seen in adults.³⁸

Gross hematuria is a reliable sign of bladder injury, occurring in 95% of patients, and in the setting of blunt or penetrating trauma should prompt evaluation using cystography, urethrography, or both.^{39,40} Acutely, patients presenting with bladder injury may complain of inability to void or suprapubic pain, though these symptoms may be masked by pain from more significant injuries.³⁵ With delayed presentation, frequent symptoms are abdominal distention, ileus, fever, or urinary ascites as a result of persistent leakage, pelvic urinoma, or abscess formation. If concomitant bladder neck injury occurs, voiding dysfunction may be present as well. Laboratory analysis demonstrates acidosis, hyperkalemia, hyperchloremia, hyponatremia, and uremia with intraperitoneal bladder injuries because of the frequency of these injuries with pelvic fracture. Particular attention is paid to thorough evaluation of the lower urinary tract for concurrent injury. Penetrating and iatrogenic trauma to the pelvis or perineum generally results in associated visceral, urethral, or genital injuries, but without bony disruption.⁴¹

Imaging of the bladder, if indicated, consists of cystography, and is performed in the clinically stable patient. Harborview Medical Center criteria for bladder imaging after blunt trauma include pelvic ring fracture with greater than 30 RBC/hpf or gross hematuria; an additional indication is the presence of a free intraperitoneal low-density fluid collection within the first 24 hours postinjury. Isolated acetabular fractures without pelvic ring involvement do not need cystography without other indications. CT cystography is used more liberally because of the central role of CT scanning in trauma assessment.⁴² For CT cystography, the bladder is filled retrograde with contrast and the scan is performed after 300 to 400 mL of contrast is instilled. Static cystography (consisting of a scout pelvic image and a second image with 300 to 400 mL of contrast instilled in the bladder) remains an acceptable means of assessing for bladder rupture. Postdrainage films are essential for static cystography, and oblique images may identify posterior defects.³⁷ Extraperitoneal contrast extravasation is confined to the pelvis on CT and appears as a “flame-shaped” opacity on static cystography (Fig. 24.4). Characteristic patterns of intraperitoneal contrast extravasation include pooling

FIGURE 24.4. Computed tomography cystography for extraperitoneal bladder injury.

FIGURE 24.5. Computed tomography cystography for intraperitoneal bladder injury.

in the cul-de-sac, paracolic gutter, or retrohepatic space on CT or outlining of bowel loops on static cystography (Fig. 24.5).

Most extraperitoneal bladder injuries can be managed conservatively with catheter drainage. Indications for repair of bladder injury are intraperitoneal bladder injury; exploratory laparotomy for concomitant injuries; penetrating bladder trauma; extraperitoneal bladder injuries with concomitant vaginal, rectal, bladder neck injury, foreign body, or bony spicules protruding into the bladder lumen; and open reduction internal fixation (ORIF) for pelvic fractures (in an effort to reduce secondary contamination of orthopedic hardware). Delayed exploration, reconstruction, or drainage may be required to remedy problems that fail to resolve with conservative measures or are diagnosed in a delayed fashion. During exploration and repair, when possible, avoid disruption of a pelvic hematoma, which may cause significant hemorrhage. The ureteral orifices and bladder wall are inspected through an anterior cystotomy or the laceration/injury itself. Sites of injury within the bladder lumen are repaired with 3–0 interrupted full-thickness synthetic absorbable suture, while the cystotomy, external injuries, or perforations are closed with a two-layer running fashion using 2–0 synthetic absorbable suture. Foley drainage alone is adequate in most cases. Suprapubic catheter diversion using a Malecot catheter (22 to 24 French) is used when irrigation for heavy bleeding is required.⁴³ Closed suction drains are placed away from the site of repair and can be removed in 48 hours unless the drainage fluid demonstrates a creatinine level higher than serum. The urethral Foley catheter is usually left in place for 7 to 10 days and removed following cystogram demonstrating a healed, watertight repair.

Urethra

The anatomy of the urethra varies throughout its course and is divided for practical purposes into the anterior and posterior segments (Fig. 24.6). The mechanism of injury varies depending on the segment, but most commonly is due to blunt mechanisms. Anterior urethral injuries are the result of straddle-type falls or blows to the perineum. Posterior urethral injuries are often associated with pelvic fracture and involve varying degrees of prostatomembranous distraction.⁴⁴ Female urethral injuries are uncommon, 0% to 6%, and are usually associated with pelvic fracture and resultant laceration by bony fragments.⁴⁵ Gross blood at the urethral meatus in males is the most reliable sign and warrants evaluation for injury. Females

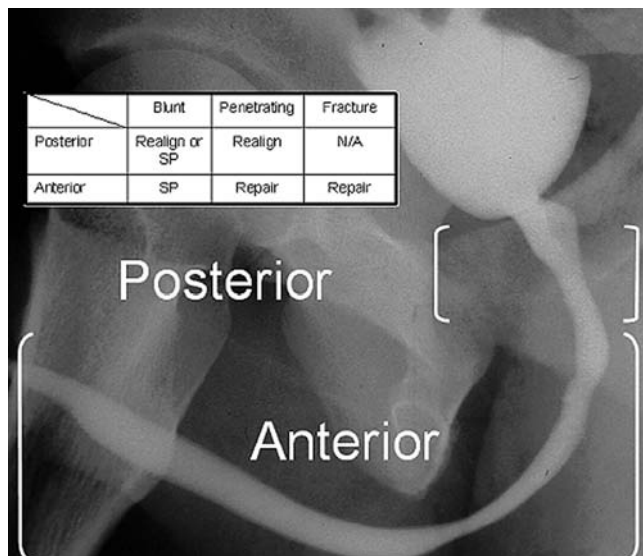

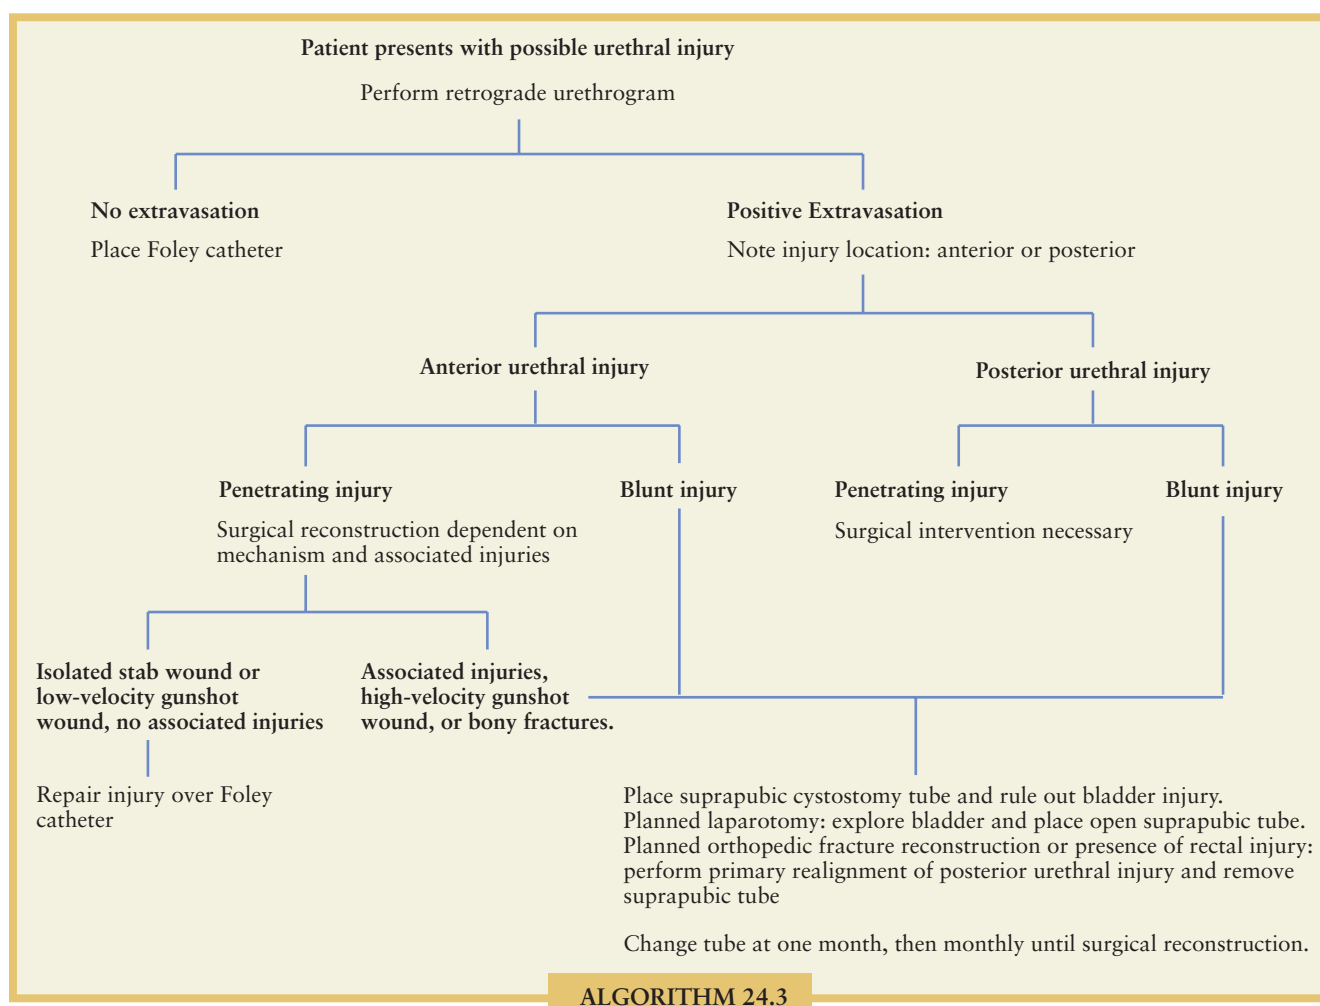

FIGURE 24.6. Normal retrograde urethrogram and management by segment and mechanism of injury.

with vaginal bleeding and pelvic fracture should be evaluated for gynecologic as well as urethral injuries. Further examination includes digital rectal examination evaluating for hematoma, bony spicules, Hemoccult blood, or a “high-riding prostate.” These findings on examination and the presence of perineal ecchymosis or scrotal hematoma suggest anterior pelvic disruption and urethral injury (Algorithm 24.3).

When gross blood is present at the urethral meatus, retrograde urethrography (RUG) is indicated before catheterization.^{46,47} RUG is readily performed using portable fluoroscopy in the emergency department or operating room. The fossa navicularis is occluded with the partially filled (2- to 3-mL) balloon tip of the catheter, the penis is stretched, and contrast is gently injected, opacifying the urethra. Oblique images are taken, when possible, to establish the absence of or the presence and location of extravasation, which is indicative of injury. If no extravasation is present, the catheter is advanced into the bladder. Failure to recognize these types of injuries can result in conversion of a partial injury to a complete injury if blind catheter placement is performed.³⁶ Early management of most posterior urethral injuries involves urinary diversion with a suprapubic catheter. Grades I and II urethral injuries can be managed without a catheter provided the patient can void. Partial anterior injuries are managed with a urethral catheter alone, and a pericatheter urethrogram is done at 7 to 10 days to confirm healing before its removal. Whereas primary débridement and closure with diversion are advocated

for anterior stab wounds or low-velocity gunshot wounds, high-velocity injuries should be managed with a suprapubic catheter and delayed reconstruction.⁴⁸ Most posterior injuries can be managed with urinary diversion and delayed (3 to 6 months) reconstruction following resorption of the pelvic hematoma. Aggressive early operative reconstruction is discouraged, although endoscopic techniques of primary realignment show promise in potentially decreasing rates of stricture formation while providing equivalent results with regard to continence and erectile dysfunction.⁴⁹ Early realignment is achieved employing endoscopes and fluoroscopy, then placing a catheter, by Seldinger technique, over a guidewire.⁵⁰ This has become a more commonplace method of initial urethral repair at high-volume trauma centers. Whether a patient receives a suprapubic cystostomy tube or a urethral Foley catheter as drainage, an appropriate plan of follow-up for tube changes, removals, and definitive reconstructive efforts is imperative, due to potential morbidities including infection, encrustation, hematuria, and obstructive uropathy. When definitive reconstruction is planned, antegrade voiding cystourethrography and retrograde urethrography are performed.

CHAPTER 25 ■ VASCULAR TRAUMA

BENJAMIN W. STARNES

KEY POINTS

- 1 The overwhelming majority of vascular injuries can be diagnosed with a thorough history and physical examination and a high clinical index of suspicion.
- 2 Contrast arteriography is the traditional “gold standard” for diagnosing vascular injury, whereas computed tomography angiography can be rapidly obtained, provides more information about other injuries, and is less invasive with fewer complications.
- 3 Threat to life or limb from active hemorrhage is self-evident.
- 4 The management of injured extremities is superseded by the management of the overall patient: “life over limb.” Limb salvage is a treatment modality not to be taken lightly or as a mandatory preference.
- 5 The guiding principle for the management of vascular injuries is proximal and distal control of the injured vessel.
- 6 The ascending aorta and innominate and right subclavian arteries are best approached by median sternotomy. The proximal left subclavian artery and descending thoracic aorta are best approached via left thoracotomy.
- 7 Left colon mobilization is useful for exposure of the paravisceral aorta, left renal artery, infrarenal aorta, and left iliac artery. Similarly, the inferior vena cava, right renal artery, infrarenal aorta, and right iliac artery can be approached by an extensive Kocher maneuver and mobilization of the right colon.
- 8 Endovascular repair of traumatic thoracic aortic disruption is associated with lower mortality and lower rates of paraplegia than traditional open repair.

A large body of literature currently exists regarding the management of traumatic vascular injuries with traditional open surgical techniques. Likewise, there is an evolving literature on the management of vascular trauma with endovascular techniques. Over the past several decades, catheter-based and endovascular techniques have been used with increasing frequency for the management of trauma. This is particularly true for the management of solid organ injury and vascular injuries resulting from pelvic fracture. The endovascular management of vascular trauma seems particularly appealing in the management of blunt truncal injuries, especially in the setting of severe concomitant brain and lung injury. Extremity and neck injuries are currently best handled by traditional methods of surgical proximal and distal control, the exception to this being base-of-skull injuries where there is no ability for distal vessel control and “watershed” areas between the trunk and extremities where surgical management for the unfamiliar surgeon can be quite difficult. This chapter reviews current literature with regard to broad principles of both open and endovascular management of traumatic vascular injuries with regions being broadly defined as neck, trunk, and extremity.

EPIDEMIOLOGY OF VASCULAR INJURY: DISTRIBUTION OF INJURIES

Trauma is the leading cause of death in persons under the age of 45 and consumes an enormous amount of health care dollars in terms of acute and long-term care. Vascular injury in particular is highly morbid and can lead to rapid exsanguination under certain circumstances. In a review of 5,760 cardiovascular injuries sustained by 4,459 patients, Mattox et al. described the predominantly young male population presenting with a majority (90%) of penetrating injury.¹ Truncal (including neck) vascular injuries predominated at 66%, with lower extremity regions representing only 19% of all vascular injuries. The mechanism of vascular injury varies, with most

being caused by high- or low-velocity weapons (70% to 80%) (Fig. 25.1). This is followed by stab wounds (10% to 15%) and blunt trauma (5% to 10%).¹

PHYSIOLOGIC CONSEQUENCE OF VASCULAR INJURY

The principal physiologic consequence of vascular injury results from either profound hemorrhage with associated metabolic consequences of total body ischemia or end-organ ischemia of the vascular bed fed by the injured vessel. Factors affecting ischemic tolerance include the nature of injury (complete vs. incomplete disruption), adequacy of collateral blood flow, underlying metabolic state, associated injuries, sensitivity of the end organ to ischemia, and the time required to repair the injury. The brain is the most sensitive tissue to ischemia due to the high basal energy requirements and the absence of robust glycogen stores. Warm brain ischemia lasting longer than 6 minutes results in irreversible injury. Other than bone, skeletal muscle is probably most resistant to ischemia. Peripheral nerves and muscle can tolerate up to 6 hours of ischemia without permanent damage.

Tissue ischemia causes anoxic cell death. Restoration of oxygen-rich blood flow after ischemic injury produces a reperfusion injury mediated by oxygen-free radicals.² These oxygen-free radicals initiate multiple proinflammatory processes, including lipid peroxidation, which causes diffuse injury to the microvasculature resulting in increased permeability, edema formation, and an increase in interstitial pressure. This overall process ultimately leads to stasis within the microvasculature, worsening ischemia, and cell lysis, including rhabdomyolysis. The resultant tissue destruction causes hyperkalemia, metabolic acidosis, and myoglobin-induced renal failure and may ultimately prove fatal.

DIAGNOSIS OF VASCULAR INJURY

- 1 The overwhelming majority of vascular injuries can be diagnosed with a thorough history and physical examination and

FIGURE 25.1. Three high-velocity gunshot wounds to the right lower extremity emphasizing a remarkable level of tissue destruction. **A:** Single entrance wound below knee. **B:** Two entrance wounds in proximal thigh. **C:** Notice the stellate appearance of the exit wounds.

high clinical index of suspicion. A history of pulsatile bleeding or, alternatively, a description of a large amount of blood at the scene of injury should elicit suspicion for vascular injury. Victims of a high-speed motor vehicle crash or those who fall from extreme heights must be assumed to have significant vascular injury until proven otherwise.

Physical examination findings are extremely variable but should be categorized according to “hard” and “soft” signs for vascular injury. Hard signs suggesting a vascular injury include pulsatile bleeding, expanding hematoma, palpable thrill, audible bruit, and evidence of ischemia as dictated by the six “P’s”: pulselessness, pain, pallor, paresthesia, paralysis, and poikilothermia. Soft signs of vascular injury include a history of moderate hemorrhage, injury in proximity to a named vessel, decreased but present pulse, nonexpanding hematoma, and associated peripheral neurologic deficit.³ The presence of distal pulses can be deceiving and are intact in up to 20% of cases of major proximal vascular injury.

Intracavitary vascular injuries should be suspected in those patients presenting with hypotension and evidence of penetrating injury to the torso. A history of rapid deceleration or high transfer of kinetic energy, as occurs with a high-speed motor vehicle crash, should also elicit suspicion for a truncal vascular injury. Common findings associated with thoracic aortic injury include first rib fracture, thoracic spine fracture, flail chest, and sternal fracture. A widened upper mediastinum on anteroposterior chest radiography, loss of normal aortic contour, or thoracic outlet hematoma may suggest significant aortic injury.

The proper measurement of the ankle-brachial index (ABI) is essential for diagnosing more occult vascular injuries. The ABI is measured by obtaining the highest arterial occlusion

pressure utilizing a manual blood pressure cuff at the ankle and a 9-MHz continuous wave Doppler probe placed over both the dorsalis pedis and posterior tibial arteries. This pressure value is then divided by the highest brachial systolic blood pressure, thereby providing the corresponding index. A normal index is greater than 1.0, and any index below 0.9 in an otherwise healthy patient is an indication for more definitive diagnostic tests to include duplex ultrasonography and/or arteriography.^{4,5} Hypovolemic patients may have values as low as 0.75 and thus should undergo repeat measurement after resuscitation or further workup if not equally low in both extremities. Repeat physical examinations, coupled with repeat ABI measurements after therapeutic intervention, to include realignment of long bone fractures, are of paramount importance.

Arteriography remains the “gold standard” for diagnosing vascular injuries and providing a road map to guide surgical repair (Fig. 25.2). Standard arteriography is not always feasible or even practical in the multiply injured patient and is certainly not always indicated for single-level injury with associated hard signs of vascular trauma.⁶ However, it can prove invaluable in the management of patients presenting with multiple levels of penetrating injury. Arteriography has traditionally been considered mandatory for patients presenting with complex knee injuries and/or posterior knee dislocations, although more recently, selective duplex examination has been used in patients with an otherwise normal vascular examination. Contrast arteriography has traditionally been the “gold standard” for diagnosing vascular injury, whereas computed tomographic angiography (CTA) is highly sensitive and specific, can be rapidly obtained, provides more information about other injuries, and is less invasive with fewer complications.^{7,8}

FIGURE 25.2. Arteriogram demonstrating vascular injury to the proximal popliteal artery as a result of distal left femur fracture.

PRINCIPLES OF MANAGEMENT

As stated previously, time is of the essence with patients presenting with vascular injury, and different vascular beds have different tolerance to ischemia. Preoperative antibiotics should be administered to all of these patients and every effort should be made to avoid vascular reconstruction in the setting of heavy contamination or simultaneous pancreatic injury. Patients with suspected vascular injuries should be prepared for operation with standard surgical approaches in mind and with additional preparations allowing for access of more proximal vascular control. In addition, preparation should be made for recovery of an adequate vein from an uninvolved extremity to be used as a reconstructive conduit. Hence, patients with suspected vascular injuries in the neck or upper extremity should have the entire chest prepped into the field to allow for rapid performance of median sternotomy or thoracotomy, as well as preparation of one or both of the lower extremities to allow for recovery of the greater saphenous vein for conduit. Patients with suspected abdominal vascular injuries should have the chest, abdomen, and both groins prepped. Patients with suspected lower extremity vascular injuries should have the abdomen and both lower extremities circumferentially prepped into the field. When managing a vascular injury in a lower extremity, the greater saphenous conduit should be obtained from the uninjured extremity.

The phrase “damage control” implies a rescue situation in which prevention of further injury is achieved. When applied to vascular injuries, damage control is defined as control of exsanguinating hemorrhage, rapid restoration of blood flow to an ischemic vascular bed, and prevention of further injury such as extremity compartment syndrome. Danger from active hemorrhage is self-evident. When dealing with the multiply injured patient, limb salvage may be a secondary priority or not a priority at all depending on the physiologic status of the

4 patient.⁹ The management of injured extremities is superseded by the management of the overall patient: “life over limb.” Limb salvage is a treatment modality not to be taken lightly or as a mandatory preference.

5 Proximal and distal control is a basic tenant of vascular
6 surgery. The ascending aorta and innominate and right subclavian arteries are best approached by median sternotomy. The proximal left subclavian artery and descending thoracic aorta
7 are best approached via left thoracotomy. Left colon mobilization is useful for exposure of the paravisceral aorta, left renal artery, infrarenal aorta, and left iliac artery. Similarly, the inferior vena cava (IVC), right renal artery, infrarenal aorta, and right iliac artery can be approached by extensive Kocher maneuver and mobilization of the right colon.

For those surgeons not accustomed to conducting a vascular surgical procedure, remote proximal control offers the best opportunity for success in managing extremity vascular injuries. For upper extremity injuries, proximal control can be obtained by exposing the subclavian artery utilizing a supra- or infraclavicular incision depending on the comfort level of the operating surgeon. The subclavian artery is notoriously fragile and thus dissection should be performed carefully in the stable patient. For the unfamiliar surgeon, an infraclavicular incision is preferred over the more hazardous supraclavicular incision. For lower extremity injuries, proximal exposure of the common femoral artery allows controlled dissection about the more distal injured vessel and provides the opportunity to perform arteriography. The challenging injury directly to the femoral triangle requires a lower abdominal oblique incision (transplant incision), with division of all three abdominal muscular layers and dissection within the preperitoneal space to expose the distal external iliac artery, which can then be rapidly and easily controlled using digital compression against the iliac fossa.

As a rule, longitudinal incisions over named vascular structures allow for the widest exposure and best control. Curvilinear and “lazy S”-type incisions should be made across joints to include the antecubital and popliteal fossa. The posterior approach to the traumatic popliteal artery injury is rarely used in any setting. Exposure can often be demanding, particularly in the setting of debris, dirt, bone dust, and bone fragments in a wound. This presentation demands the time-honored tradition of adequate and aggressive débridement of devitalized tissue.

Systemic heparinization (50 to 75 U/kg intravenously) should be initiated in stable patients in whom vascular control of the injury has been quickly established, estimated prehospital blood loss is relatively low, and ongoing bleeding sources are minimal. Unstable patients with diffuse hemorrhage from bone fragments, torn muscle, and additional injuries and patients who are already hypothermic and coagulopathic should not get systemic anticoagulation during repair of a vascular injury. Alternatively, local administration of heparinized saline solution directly into the injured vessel prior to repair may aid in preventing thrombotic complications. The decision to anticoagulate is left to the discretion of the operating surgeon, who must be in close contact with the anesthesia providers in order to fully understand the patient’s clinical status.

As with all vascular operations, there are several important elements for success. Key among these is careful handling of tissue, use of magnification loupes, adequate lighting, and use of fine instruments with fine, monofilament suture. After exposure, injured vessels should be carefully débrided back to normal- and healthy-appearing tissue. Inflow and back-bleeding should then be assessed. If there is no back-bleeding, gentle thrombectomy with appropriate-sized Fogarty embolectomy catheters should be performed. The use of a standard pulmonary artery catheter may be useful in this scenario if no standard embolectomy catheters are available.¹⁰ Minimal manipulation of intima is imperative to prevent

TABLE 25.1 TREATMENT**TREATMENT OF VASCULAR INJURY**

■ TYPE OF REPAIR	■ USES AND INDICATIONS
Lateral repair	When vessel not compromised >25% circumference
Patch angioplasty	When vessel not compromised >50% circumference
Primary end-to-end anastomosis	<2 cm defect, mobilize ends, spatulate
Interposition graft	>2 cm defect, reversed vein > polytetrafluoroethylene, most common repair
Extra-anatomic bypass	Extensive defect, multiple-level injury, contamination
Suture ligation	Strongly consider prophylactic fasciotomy, distal embolectomy, and anticoagulation

vessel thrombosis in the early postoperative setting. After adequate débridement, the vessels should be flushed with a heparinized saline solution both proximally and distally. A tension-free repair should then ensue. Options for repair are many and are listed in Table 25.1. As a general rule, the most often utilized vascular procedures are ligation and interposition bypass graft. With combined injuries, arterial repair should precede venous repair except when venous repair requires little effort. This is to minimize ischemic burden from an already severely injured vascular bed.

The temptation to reconstruct, repair, or even ligate an arterial injury in the setting of a highly contaminated wound should be thoroughly resisted. Recent studies have shown that a high failure rate ensues due to infection and subsequent thrombosis.¹¹ In a contaminated wound, every effort should be made to perform adequate débridement and then reassess for adequate collateral macroperfusion with every means available. If ligation of a major artery is required, distal embolectomy should be routinely performed followed by distal infusion or systemic administration of heparin to preserve collateral circulation.¹² If feasible, patients should undergo abdominal decompression, prophylactic fasciotomy, observation, and then definitive revascularization once control of wound sepsis has been accomplished. Alternatively, routing of bypass grafts through uncontaminated fields offers the best chance for success in the management of these challenging injuries.

Key to the success of vascular repair is appropriate use of available conduit for reconstruction. It is widely held that the best alternative conduit for reconstruction is autologous saphenous vein. The saphenous vein is the workhorse for vascular surgeons and can be used in multiple locations. It is important to remember the concept of directional flow within veins and thus reverse or turn around the saphenous vein prior to using it as a conduit for revascularization. The saphenous vein may also be used as patch material or refashioned in the form of a panel or spiral graft for reconstruction of larger vessels. The saphenous vein should always be recovered from the uninvolved extremity. This is done to provide maximal venous drainage from the injured extremity should the deep system be involved or the patient develop deep vein thrombosis in the postoperative period. Proximal saphenous vein can still be utilized in the rare patient presenting with upper extremity vascular injury and bilateral major traumatic below-knee injuries.

The repair of extremity venous injuries has been controversial. Data from Dr. Norman Rich and the Vietnam Vascular Registry supports an effort at repair of most major venous injuries if

possible.^{13,14} The decision to repair versus ligate a major extremity venous injury depends on the available resources, existing comorbidities, coexistent injuries in the same patient, and, of course, the hemodynamic stability of the patient. Rich retrospectively demonstrated a lower incidence of chronic venous insufficiency and postphlebotic syndrome in those patients undergoing venous repair as opposed to ligation in the lower extremity.¹³ However, the same general principles do not hold true for venous injuries in the upper extremity, where ligation is better tolerated with minimal chronic morbidity.

OPERATIVE MANAGEMENT OF SPECIFIC REGIONS

Management of Vascular Injury in the Neck

Injuries to the neck have been notoriously difficult to manage. A clear anatomic division of the neck into zones has allowed a selective approach to penetrating neck trauma. Zone I lies below the cricoid cartilage, and zone III lies above the angle of the mandible. Zone II, which is between I and III, has classically been managed with immediate exploration and direct evaluation of the aerodigestive tract and the carotid and jugular vessels. The most commonly injured structures in the neck are the blood vessels, with the incidence of major vascular trauma following penetrating neck trauma being 20%.¹⁵ Physical examination and determination of hard signs predict those patients with significant injuries who might benefit from immediate exploration.¹⁶ Direct surgical repair remains the “gold standard” for injuries in all zones, but endovascular approaches are appealing in that some of these injuries can be remotely approached from within the thoracic inlet and base of the skull, thus avoiding the morbidity of the required extensive surgical exposure. Unique advantages for an endovascular approach to the extracranial cerebrovascular system include avoidance of general anesthetic and the ability to monitor neurologic status during the intervention.

Penetrating zone I and III injuries that require immediate operative intervention are not candidates for a purely endovascular approach. However, endovascular techniques may be utilized in a “hybrid” fashion to support the standard open repair of these injuries. Zone I injuries with hard signs of vascular injury may have an enlarging hematoma at the thoracic inlet, high chest tube output, or shock. These injuries notoriously involve the great vessels. Immediate control involves a high anterior thoracotomy, sternotomy, or clavicular resection to obtain adequate proximal control. Once the patient is prepared in the operating room, an occlusion balloon can be rapidly utilized from the groin to provide endoluminal proximal control of the great vessels, allowing conduct of a surgical exposure in a more controlled fashion and possibly avoiding sternotomy for proximal exposure. With an occlusion balloon in place, an arteriogram will help locate the injury and allow for operative planning. After the injury is exposed, a vascular clamp replaces the occlusion balloon, or, alternatively, if proximal vessel length is not adequate, the occlusion balloon remains in place for repair.

In patients with soft signs of a cervical vascular injury and hemodynamic stability, there is ample time for further evaluation. Arteriography may identify an intimal flap, dissection, pseudoaneurysm, complete or partial transection, or thrombosis. Operative repair of these lesions has been shown to reduce overall mortality and stroke rates for both penetrating and blunt trauma as compared to observation or ligation.¹⁷ However, several centers have found that early anticoagulation alone also improves overall neurologic status and mortality in a cohort of patients with high internal carotid artery trauma who did not undergo operative repair and were able to tolerate anticoagulation with heparin.^{18–20}

Vertebral artery injury is a rare occurrence, but the identification of vertebral artery injuries has actually increased owing to the liberal use of screening tests (ultrasound or CTA) during workup. When encountered, vertebral artery injuries can be difficult to expose and control. The first portion of the vertebral artery is fairly accessible, but once the vessel enters the bony foramen of the cervical canal, blind clipping or packing with bone wax carries the risk of cervical nerve root damage. Transcatheter embolization has been utilized for vertebral artery transections, pseudoaneurysms, and arteriovenous fistulas with a combination of embolization techniques including wire-guided crossing of a transected vessel to gain occlusive control of the distal bleeding vessel.^{21–24}

Management of Vascular Injury in the Trunk

Truncal vascular trauma is a highly lethal event. The majority of patients experiencing blunt or penetrating injury to the aorta in either the chest or abdomen do not routinely survive to reach a higher level of care and often die in the field. A blunt mechanism of injury associated with rapid deceleration also causes predictable injury patterns within the thoracic and abdominal aorta and iliac, renal, and visceral arteries. Associated severe brain and lung injury directly and indirectly increase the perioperative risk associated with general anesthesia and a traditional open surgical approach.

Management of Vascular Injury in the Chest

Blunt aortic injury (BAI) is a highly lethal event, with 80% to 85% of patients expiring at the scene of injury. Of those presenting to a trauma center, 40% to 50% die within 24 hours of injury.²⁵ Conventional treatment involves thoracotomy for open repair, with associated mortality rates ranging from 15% to 28% and paraplegia rates as high as 19%.²⁶ In patients experiencing traumatic thoracic aortic injury, thoracotomy may worsen potential associated lung injuries and increase mortality risk.²⁷ The past decade has seen significant advances in the endovascular management of BAI with resultant dramatic decreases in morbidity and mortality. U.S. Food and Drug Administration (FDA)-approved devices are now commercially available in the United States for the endovascular repair of thoracic aortic pathology. During the evaluation and early care prior to surgery for these injuries, control of the shear forces on the disrupted aorta using beta-blockers is mandatory. Systolic blood pressures should be maintained at about 100 mm Hg.

In March 1997, Fabian et al. published a landmark prospective study of BAI inclusive of 50 trauma centers across North America now referred to as the American Association for the Surgery of Trauma 1 (AAST-1) trial.²⁸ There were 274 cases of blunt aortic injury studied over 2.5 years with average time from injury to repair of 16.5 hours. Overall mortality was 31%, with 63% of deaths attributable to aortic rupture. Of patients presenting in extremis or who sustained rupture while waiting for surgery, the mortality was 100%. Postoperative paraplegia occurred in 8.7% of patients. Ninety-three percent of injuries occurred at the proximal descending aorta in the region of the aortic isthmus.²⁸ Two months after this landmark publication, Semba et al. reported their initial experience using endoluminal grafts to repair a multitude of aortic pathology.²⁹ In their series of 95 patients, one patient underwent endoluminal repair for blunt aortic injury and survived. Since then, the use of endovascular techniques to manage this devastating injury has increased. An endovascular approach for repair of blunt thoracic aortic injury decreases the morbidity associated with posterolateral thoracotomy and single-lung ventilation in patients who often have multiple associated injuries, including rib fractures, flail chest, or pulmonary injury (Fig. 25.3).

Recently, the AAST Multi-institutional Thoracic Aortic Injury Study Group published the results of the AAST-2 trial. Over a period of 26 months, 193 patients with BAI from 18 centers were studied. Over 65% of the injuries were managed with endovascular repair with a resultant decrease in mortality from 22% to 13% and a reduction in paraplegia rates from 8.7% to 1.6%.³⁰ Endovascular repair of traumatic thoracic disruption is associated with lower mortality and lower rates of paraplegia than traditional open repair. These findings are extremely compelling and should elicit a dramatic shift in the primary management of BAI by surgeons caring for this patient population.

A majority of patients experiencing BAI are young and hence have small aortic anatomy. Most commercially available grafts are designed for the treatment of aneurysmal disease and not meant for young aortas. The smallest commercially available grafts specifically designed for the thoracic aorta are 22 mm (Talent; Medtronic/AVE, Santa Rosa, CA) and 26 mm (TAG; W.L. Gore, Flagstaff, Arizona). Most experts would recommend an oversizing of 10% to 15% based on the aortic diameters defined in the landing zones for BAI. Aggressive oversizing has led to stent graft failures and “infolding” of the grafts with resultant endoleak and collapse.^{31,32} A variety of different infrarenal “cuffs” and limb extensions have been used by some authors to avoid these problems in small aortas.³³

Not all patients presenting with blunt aortic injury should be considered for endovascular repair. Some authors have

FIGURE 25.3. A: Axial computed tomography angiography (CTA) image of blunt aortic injury. B: Oblique sagittal CTA image of the same injury. C: Follow-up CTA reconstruction after successful stent graft repair.

advocated using the Injury Severity Score (ISS) to guide therapy.²⁷ A predicted mortality based on an ISS of greater than 100% should elicit an approach to simply supporting the patient with conservative measures, including long-term control of blood pressure with beta-blocking agents and other antihypertensive agents as required in the resistant patient.

Management of Vascular Injury in the Abdomen

The management of abdominal vascular trauma is a formidable challenge faced by many trauma surgeons. In a review of 5,760 vascular injuries in 4,539 patients, Mattox et al. described abdominal vascular injuries accounting for 33.7% of all vascular injuries.¹ Abdominal vascular injuries remain the most common cause of death following penetrating abdominal trauma. Many patients experiencing abdominal vascular injury, whether penetrating or blunt, have simultaneous hollow viscus injury, which makes operative management difficult when considering the need for prosthetic graft placement in a potentially contaminated field.

The so-called “seat belt aorta” is defined as injury to the aorta after direct compression against the bony structures of the spine. The most common site of this injury is directly below the inferior mesenteric artery. Atherosclerotic aortic plaques are also thought to be a contributing factor because less force is required to damage the aortic intima with an existing rigid plaque within the lumen.³⁴ It has been strongly suggested that an initial attempt at endovascular repair be made for blunt abdominal aortic injury. This approach is less invasive, avoids a retroperitoneal dissection and application of an aortic cross-clamp, and may be performed immediately after closure of a laparotomy for grossly contaminated injuries.³⁵

Blunt trauma is the most common method of injuring a renal artery. There are only a few isolated reports in the literature describing renal artery stenting for traumatic injury with either balloon-expandable or self-expanding stents.^{36–38} Potential benefits to this approach include the rapidity with which repair can be accomplished following the diagnosis by conventional or CTA. Unfortunately, in a majority of these injuries, the diagnosis is often delayed, which significantly impacts outcome for the affected kidney. While nonoperative complication rates, even with close and careful observation, have been reported to be as high as 82%,³⁹ treatment remains controversial when the end organ is not threatened. Most groups recommend treatment within 6 to 12 hours as the most critical factor in preserving renal function.⁴⁰

Injuries to the celiac or superior mesenteric artery are best managed with traditional open surgical exposure and ligation and/or repair. Endovascular management of acute traumatic injury to these arteries has not been described as yet. Reasons for this probably stem from a requirement for assessment of bowel viability in conjunction with definitive arterial repair. The combination of endovascular and laparoscopic techniques in approaching these injuries may prove worthwhile in the future.

Iliac artery injuries are among the most challenging for trauma surgeons. Morbidity and mortality rates from these types of injuries approach 15% and 40%, respectively.^{41,42} Proximal and distal control can be exceedingly difficult, while the utility of angiographic embolization of bleeding pelvic vessels in association with severe blunt pelvic trauma is well documented. As with the thoracic and abdominal aorta, blunt trauma is an infrequent cause of iliac vascular injury. However, morbidity and mortality associated with such injuries are profound. Like the abdominal aorta, the presence of atherosclerotic plaque within the iliac vessels has been associated with an increased susceptibility to intimal disruption.⁴³ Lyden et al. reported on the successful management of common iliac artery dissection with self-expanding stents after

blunt abdominal trauma.⁴⁴ Long-term follow-up is not available for iliac stenting in the setting of injury from blunt arterial trauma; however, one would surmise that long-term patency rates are not too dissimilar and perhaps better than those from standard iliac artery angioplasty and stenting.

Injury to the vena cava is a rare event, occurring in 0.5% to 5% of penetrating injuries and 0.6% to 1% of blunt abdominal injuries.⁴⁵ Despite their rarity, injuries to the vena cava represent 30% to 40% of all abdominal vascular injuries and are commonly associated with a mortality as high as 50%.⁴⁶

Management of Vascular Injury in Watershed Regions

Managing injuries to the thoracic outlet often requires incisions that are potentially profoundly morbid. Many injuries in this location are fortunately contained hematomas that allow for definitive preoperative diagnosis. This may allow for a window of opportunity to use endovascular techniques to manage supra-aortic truncal injuries to the innominate, carotid, or subclavian arteries while avoiding a thoracotomy.^{47,48} Likewise, iliofemoral injuries are also difficult to control. A multicenter trial evaluated the use of Wallgraft Endoprostheses (Boston Scientific, Natick, Massachusetts) for the management of 62 patients with iliac, subclavian, or femoral arterial injuries.⁴⁹ While the majority (78%) of these injuries were iatrogenic in nature and not representative of a purely primary vascular injury series, the data provide compelling support for endovascular management.⁴⁹ In this study, the majority of injuries treated were in the iliac arteries (53.2%), while the remainder were located in the subclavian (29%) or femoral (17.7%) arteries. Eighty-five percent of patients avoided surgery entirely within the first year after placement of the stent graft.

In addition, operative complications for emergent procedures with the stent graft were significantly reduced compared with those of surgical repair (21% vs. 57%), and late complications for emergent procedures were not different from the rate for surgical repair (6% vs. 12.5%). Similarly, postprocedure mortality associated with emergent stent graft procedures was significantly reduced compared with that of emergent surgical repair (9% vs. 27%), and late all-cause mortality was significantly reduced compared with emergent surgical repair (15% vs. 34%).

These data should be interpreted with caution as the numbers are small and the comparison between iatrogenic injuries and standard traumatic vascular injuries is probably incomparable. Despite these differences, endovascular therapy has become an essential tool for the trauma or vascular surgeon managing these difficult injuries.

Management of Vascular Injury in the Extremity

The Mangled Extremity Severity Score (MESS) was created as objective criteria to predict amputation after lower extremity trauma. The four criteria include (a) skeletal/soft tissue injury, (b) limb ischemia, (c) shock, and (d) patient age. An MESS score greater than or equal to 7 in the original series predicted amputation with 100% accuracy.⁵⁰ Many such scores have been developed to attempt to predict the need for urgent amputation, but this accuracy has not been reproducible. The high specificity of these multiple scoring systems confirm that limb salvage can be predicted. However, the converse is not true; low variable sensitivities fail to support their validity as a predictor of amputation and should not be used for this purpose in the individual patient.⁵¹

The overwhelming majority of injured extremities requiring vascular repair for limb salvage will involve the common

femoral, superficial femoral, popliteal, axillary, or brachial arteries. Isolated injuries to the ulnar, radial, and tibial arteries can be managed with arterial ligation in a majority of cases, as long as at least one vessel is patent to perfuse the extremity. In general, incisions of election should be made as a preference over incisions of opportunity provided by an existing wound. This is not always possible as the wound may provide adequate exposure for definitive control of the vascular injury.

The use of a tourniquet has long been a controversial topic. Inappropriately applied tourniquets actually cause an increase in bleeding from an extremity wound. This paradoxical effect results from occlusion of the lower-pressure venous outflow and inadequate occlusion of the higher-pressure arterial inflow. As a result, an increase in the bleeding from the wound can lead to early exsanguination. A properly applied tourniquet causes a significant amount of pain, which should be managed with intravenous or intramuscular pain medication. The temptation to remove a properly placed tourniquet due to patient discomfort should be resisted until operative control has been achieved. Tourniquets are often applied to hypotensive patients prior to resuscitation, and hence less pressure is required to arrest arterial hemorrhage. Once resuscitation is initiated and more normal systolic pressures are achieved, patients may bleed through their tourniquet. Thus, tourniquets should be monitored and tightened for effectiveness. In the emergency department, pneumatic tourniquets can be used as a proximal clamp for temporizing measures in the multiply injured patient with ongoing workup and those with massive soft tissue destruction and mangled extremities.

Temporary intraluminal shunts allow for rapid restoration of blood flow to an ischemic limb or vascular bed while other procedures to include wound débridement, external fixation of fractures, or more lifesaving procedures such as trauma laparotomy or thoracotomy can be accomplished.^{52–54} Shunts may be easily and rapidly placed after proximal vascular control with either a pneumatic tourniquet or vascular clamp and secured in place with Rummel tourniquets or simple silk ties to prevent dislodgement. After placement, patency should be confirmed with intraoperative continuous wave Doppler of the shunt. The specific use of Sundt shunts minimizes risk of dislodgement due to their design when appropriately inserted. The Sundt shunt (Integra Lifesciences Corp., Plainsboro, New Jersey) is lined with an inner coil to prevent kinking or collapse (Fig. 25.4), except for one small area within the shunt of discontinuous coils, which should be used for clamping if needed. Clamping the shunt in any other location will crush the coil and occlude the shunt.

One of the most important factors in managing the acutely injured extremity is the liberal use of fasciotomy to avoid or treat

FIGURE 25.4. Temporary intraluminal shunt prior to definitive repair of an arterial injury.

FIGURE 25.5. Thigh fasciotomy in a patient with penetrating injury to the right lower extremity causing vascular and skeletal injury.

compartment syndrome.⁵⁵ A thorough understanding of the technique of fasciotomy for both the upper and lower extremities as well as the feet and hands is mandatory (Fig. 25.5). A key principle for performance of a standard four-compartment fasciotomy in the lower extremity includes two long skin incisions, each at least 15 cm, on both the medial and lateral aspects of each affected extremity. Indications for fasciotomy are listed in Table 25.2.

Repair of traumatic lesions using endovascular techniques has had limited application in the extremities. The acutely injured patient with hard signs of a peripheral vascular injury can usually be controlled with direct tamponade or, rarely, a tourniquet. While time is of the essence in a patient with significant ischemia or neurologic deficit, peripheral vascular beds are fairly resistant to temporary ischemic times of 4 to 6 hours,⁵⁶ and this allows the surgeon time for catheter access and endoluminal examination of the injury in the operating room. While open repair may be required for complete vessel transection, endovascular treatment or proximal control can be advantageous for a high brachial artery injury or common femoral artery injury that is associated with an extensive hematoma. This would avoid an extensive dissection near the brachial plexus and, in the groin, would avoid a suprainguinal dissection into the pelvis.

Pseudoaneurysms and arteriovenous fistulas of the peripheral vascular system occur infrequently aside from iatrogenic injuries. Iatrogenic injuries secondary to femoral access sites account for the majority of pseudoaneurysms and arteriovenous fistulas that are managed with endovascular techniques.

TABLE 25.2 INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR FASCIOTOMY

- >4–6 h evacuation delay to revascularization
- Combined arterial and venous injuries
- Crush injuries
- High-kinetic-energy mechanism
- Vascular repair
- Arterial or venous ligation
- Comatose, closed head injury, or epidural analgesia
- Tense compartments
- Prophylactic

After ultrasound-directed pressure and thrombin injection have failed to thrombose pseudoaneurysms,^{57,58} covered stents can be successfully used to exclude pseudoaneurysms from the circulation.⁵⁹ Iatrogenic vascular injuries secondary to orthopedic procedures have also been successfully managed with endovascular principles.⁶⁰

Traumatic pseudoaneurysms and arteriovenous fistulas are significantly higher in the military population as a result of fragmentation wounds⁶¹ and are only rarely encountered in civilian trauma. These injuries may not be readily apparent at the time of injury and can present several years later.^{62,63} While intimal flaps or segmental narrowing appears to resolve spontaneously, pseudoaneurysms and arteriovenous fistulas tend to enlarge, embolize, or thrombose.⁶⁴ When identified, endovascular treatment has ranged from transcatheter embolization with coils or balloons, and occasionally Gelfoam packing is required as an adjunct.⁶⁵⁻⁶⁸ Remote endoluminal occlusion in these patients either avoids an exploration in an acute grossly infected cavitary wound or avoids an incision through a scar that would have potential healing complications.

POSTOPERATIVE MANAGEMENT

Patients who have undergone repair of vascular injuries from trauma should be monitored in the intensive care unit for at least the first 24 hours after surgery. This should include electrocardiographic monitoring and pulse oximetry, particularly because hemorrhagic shock and reperfusion of an ischemic limb may result in systemic physiologic derangements such as hypoxia, hyperkalemia, and acidosis. Acidosis, anemia, and hypothermia should be aggressively corrected. For isolated extremity vascular injuries, mild coagulopathy may be tolerated after revascularization as long as continued bleeding is minimal. Patients may have substantial hypothermia, tissue edema, and vasospasm in the injured limb, making palpation of pulses difficult. Hypothermia should therefore be aggressively corrected and evaluation of vascular status should rely on Doppler evaluation with ABIs rather than palpable pulses. During this early postoperative period, palpation for distal pulses and search for Doppler signals should occur hourly. Any change at the completion of the surgical repair in pulse or particularly Doppler signals from the baseline examination warrants an investigation, either by rechecking ABIs and/or performing an arteriogram. Patients who had heavily contaminated wounds on initial presentation should have a planned return trip to the operating room within 24 hours for repeat irrigation and débridement of wounds.

MILITARY-SPECIFIC APPLICATIONS

The modern battlefield has a staunch reputation of being unclean, noisy, and lacking valuable resources.⁶⁹ In addition, high-kinetic-energy injuries such as those resulting from high explosives, munitions, and high-velocity missiles often cause soft tissue destruction that is not routinely seen in civilian settings. Extremity injuries predominate, representing 50% to 70% of all injuries treated during Operation Iraqi Freedom, and exsanguination from extremity wounds is the leading preventable cause of death on the modern battlefield.⁷⁰ Recent advances in military medicine have translated into a greater percentage of wounded soldiers surviving during Operations Enduring and Iraqi Freedom than in any other previous American conflict.⁷⁰ Despite the relative lack of proper angiographic equipment on the modern battlefield, some surgeons are challenging this standard and attempting to perform “damage control” endovascular procedures in the field. This technology cannot be ignored for future military conflicts.

Major extremity vascular injury in armed conflict represents one of the most formidable challenges for the trauma surgeon. These injuries are often present in patients with concomitant multisystem injury from fragmentation munitions. Arterial injuries are frequently associated with venous, peripheral nerve, extensive soft tissue, and skeletal injury. Combined arterial and venous vascular injuries are not uncommon and often may preclude limb salvage if not addressed. Patients with these injuries often arrive in hemorrhagic shock, and treatment of these injuries usually requires staged and multidisciplinary approaches.⁷¹

OUTCOMES

Outcomes after vascular injury are time dependent, necessitating a sense of urgency in overall management. The results of expeditiously treated vascular injuries are encouraging. Mortality rates are highest when associated with truncal vascular injuries and mostly involve the aorta or its primary branches. Most often, however, the mortality is related to other associated injuries.

The ultimate outcome measure for lower extremity vascular trauma is the functional limb preservation rate. Amputation rates after peripheral vascular trauma continue to decrease, with several modern series reporting rates of less than 2%. This decrease in amputation rate probably relates to a shortening of the duration of ischemia by improvements in evacuation, rapid diagnosis and treatment, and the use of intraluminal shunts. Early amputation is more likely if a delay in diagnosis occurs or there has been a significant blunt component (crush) to the injury. Late amputation is not well documented but is typically done for intractable pain, complex wound issues, disability, or chronic infection, which frequently includes osteomyelitis. Long-term functional outcome is not dependent on the durability of the vascular repair but, alternatively, on the integrity of the neuromuscular and skeletal elements.⁷²

CONCLUSIONS

The application of endovascular technology to the management of penetrating and blunt traumatic vascular injuries represents an exciting and significant advance in modern trauma centers. Utilization of these techniques to stabilize a patient in extremis or to serve as a “bridge” to future elective procedures represents an attractive alternative with potentially lower morbidity and mortality rates than conventional open surgical management. It is of the utmost importance that these procedures be carried out by experienced providers in a committed trauma center environment conducive to such repair. A wide variety of imaging equipment as well as endovascular inventory must be readily available for the successful management of these injuries.

Surgeons should emphasize the use of endovascular surgery as a modern “damage control” technique.⁷³ Likewise, training paradigms for the credentialing of qualified trauma surgeons should include exposure to basic endovascular techniques. It is likely that in one or two decades, all endovascular procedures relating to trauma will be performed by trauma specialists.

CHAPTER 26 ■ ORTHOPAEDIC TRAUMA

JENS R. CHAPMAN, RICHARD J. BRANSFORD, AND CARLO BELLABARBA

KEY POINTS

- 1 Orthopaedic injuries occur in 70% of multiply injured patients and, of missed injuries, 75% are orthopaedic, which mandates systematic, thorough secondary and tertiary surveys. Delayed recognition leads to potential ongoing blood loss and associated secondary insults contributing to complications, such as pulmonary failure.
- 2 Life-threatening blood loss can occur secondary to long bone fractures, which are treated by realignment, splinting, and compression wrapping; pelvic ring disruption, treated by sheet wrapping to decrease pelvic volume and stabilize fractures; and spine fracture dislocations, treated with immobilization, realignment, and airway and vascular support. Open, bleeding wounds require direct intervention, including potential amputation or completion amputation.
- 3 Making the decision to amputate is difficult but preferable to saving a disabling, nonfunctional, or painful extremity. Loss of significant tissue, prolonged ischemia, and disruption of nerves plus scores, such as the Mangled Extremity Severity Score (MESS), aid in this decision.
- 4 Compartment syndromes are defined as inadequate tissue perfusion to meet oxygen requirements resulting from increased pressure in a confined anatomic space. The earliest reliable sign is excessive pain to passive or active movement of muscles in the compartment. Pressure monitoring with pressure differences between the compartment and diastolic pressure of less than 30 mm Hg require urgent operative decompression.
- 5 Major joint dislocations such as of the hip, femoral neck fracture, open fractures with contamination, talar neck fracture with dislocation, and thoracic fracture dislocations are common injuries with potential for long-term disability that require aggressive early intervention.
- 6 Spinal cord injuries are leading causes of long-term morbidity and mortality. Aggressive prevention programs, adequate recognition and resuscitation to optimize perfusion, and timely decompression and stabilization are required to optimize recovery. The use of steroids in the management of spinal cord injuries is no longer the standard of care.

The initial resuscitation phase of an acutely traumatized patient aims to identify and treat the immediately life-threatening conditions with priorities placed on maintaining or restoring airway, breathing, and circulation. Injuries to the head, chest, and abdomen receive undisputed priority in rationale-based trauma assessment and treatment algorithms.

- 1 Musculoskeletal injuries, which have more than a 70% incidence in multiply injured patients and a high potential for considerable long-term morbidity, if not addressed properly, play an important role in successful trauma management.¹ Systematic and effective incorporation of musculoskeletal treatment algorithms in trauma assessment and care can play a crucial role in improving long-term patient outcomes and decreasing mortality. On a conceptual basis, orthopaedic injuries can be differentiated into the three general impact categories: (a) life-threatening injuries, (b) limb-threatening injuries, and (c) injuries with adverse long-term functional implications.

To minimize the effects of musculoskeletal injuries on the care of trauma patients, implementation of a protocolized approach to diagnosis is helpful. Since approximately 75% of missed injuries are orthopaedic in nature, a systematic musculoskeletal systems evaluation is recommended.²⁻⁵ Inadequate visualization of the region of injury or failure to perform a formal secondary or tertiary trauma survey are the most common causes of delay in diagnosis.

Initial musculoskeletal assessment of an acutely injured patient ideally is performed concurrently with the other components of the trauma patient evaluation, including serial documentation of vital signs and mental status and an anteroposterior radiograph of the pelvis, a lateral radiograph of the cervical spine, and an anteroposterior roentgenogram of the chest. Preferably, formal musculoskeletal systems assessment and initial care take place during the exposure of the patient, with palpation of the trunk and all extremities, manual realign-

ment of deformed limbs, palpation of pulses, and detailed neurologic examination.⁶ While maintaining full spine precautions using the multiperson team technique, a formal “log-roll” turn remains a standard procedure for full clinical trauma assessment at the earliest feasible time with full palpation of the axial spine from the occiput through the coccyx and denotation of direct or indirect injury signs. Open injuries and penetrating wounds are evaluated for their impact on the patient’s vital functions and limb viability and then are dressed sterilely and splinted until definitive care is rendered. Appropriate antibiotic management for open fractures and tetanus immunization should be administered in the emergency setting. A systematic neurologic examination and documentation are preferably performed consistent with the published standards recommended by the American Spinal Cord Injury Association, including perianal and rectal examination for presence of blood, voluntary contraction, sensation, tone, and reflexes.⁷ For all trauma patients a protocol for secondary and tertiary evaluation should be in place to minimize the occurrence and impact of delayed injury recognition. This is particularly important for patients with cognitive impairment and patients who have been removed from the normal trauma care evaluation algorithm because of exigent circumstances.

LIFE-THREATENING INJURIES

- 2 Musculoskeletal trauma may directly or indirectly lead to patient demise on an acute, subacute, or delayed basis. Acutely life-threatening conditions may arise from large-scale blood loss seen with major arterial injuries in conjunction with long bone fractures, pelvic ring disruption, or spine fracture dislocations. Subacute life-threatening circumstances may result from occult blood loss with delayed recognition and response.⁸ Delayed patient loss of life may occur as either a direct or

indirect result of musculoskeletal injuries. Secondary pulmonary deterioration and sepsis after multiple fractures are leading causes of such delayed patient loss of life. Although the exact cause of posttraumatic sepsis and pulmonary deterioration remains incompletely understood and is likely multifactorial, the timing and technique of resuscitation and musculoskeletal injury treatment, including factors such as the duration of recumbence and immobility, undoubtedly play a considerable role in the onset and prevention of these serious events.^{9–11}

Injuries to the musculoskeletal system may be of sufficient severity to cause acutely life-threatening hemodynamic instability because of hypovolemia or neurologic alterations. Injuries with disruption of vascular structures leading to acute or subacute hypovolemia include pelvic ring disruptions, multiple long bone fractures, traumatic forequarter or hindquarter amputations, scapulothoracic dissociations, and upper- to midthoracic-level fracture dislocations, as well as any form of distractive spinal column injury.^{12–15} The blood loss in each of these injuries may be occult if the injury is closed. The source of bleeding may be of arterial, venous, or combined origin, which can dissect along soft tissue planes even at low pressures into larger recesses such as the retroperitoneal pelvis, thigh, chest, or lumbodorsal fascia plane. Thus, constant suspicion of this “third-spacing” phenomenon in conjunction with severe musculoskeletal injuries remains a major differential diagnosis of hypovolemia. Diagnostic modalities such as computed tomography (CT) scans or even plain radiographs can assist in identifying such abnormal fluid collections. Aggressive countermeasures in this setting may include simple bedside measures such as temporary pressure dressings, pelvic sheet application, and limb realignment and splinting.¹⁶

A major factor affecting mortality in musculoskeletal injury has arisen with the increasing care challenges for injuries to the elderly. The adverse relationship between survival beyond 1 year following trauma for patients 80 years or older in the presence of numerous comorbidities and certain injuries, such as hip fractures, type 2 odontoid fractures, and fractures in ankylosing spinal conditions, has become an increasingly well-documented public health concern. Large-scale outcome studies continue to define the role of early aggressive multidisciplinary management versus more palliatively directed management options for this increasingly aged segment of the population.^{17–20}

However, currently for these two large populations—the multiply injured secondary to high kinetic forces and the very

elderly with low-velocity mechanisms, multiple comorbidities, and relatively trivial orthopaedic injuries—improved survival outcomes appear to be primarily attributable to multispecialty care approaches. In turn, communication between the different specialties was found to be a critical contributor to improved patient survival in comparisons of level I trauma centers to community care centers in studies comparing results from fracture care in general and for thoracolumbar fractures specifically.^{20,21}

A number of common injuries that potentially pose an immediate threat to patient survival are reviewed here.

Pelvic Ring Disruption

Open-book pelvic injuries, which characteristically consist of an anterior-posterior distractive separation of the anterior pelvic ring and external rotation of the pelvic wings, can be associated with massive diffuse venous plexus bleeding into the traumatically expanded lower abdominal cavity. Because of the typically venous nature of the associated substantial blood volume loss, attempts at stopping the hemorrhage with interventional angiographic embolization may frequently be futile. Emergent reduction and compression of this traumatically expanded space may, however, be an effective emergent management strategy. This procedure can be achieved with a number of percutaneous surgical intervention measures, such as external fixation or a pelvic clamp, which can be placed in an emergency room setting. More recently, simple application of a “pelvic sheet” has been introduced as a similarly effective non-invasive volume reduction strategy to reduce lower abdominal and pelvic volumes. This simple technique consists of wrapping a folded linen sheet around the affected patient’s pelvic ring from posterior to anterior and then clamping it tightly in front (Fig. 26.1).¹⁶ The realignment of the injured pelvis is assessed with an anteroposterior radiograph. Definitive surgical stabilization with one or more definitive management options, ranging from minimally invasive to open instrumentation techniques, can be deferred to a later time when resuscitation is completed.

Major Limb Injuries

Major blood loss may occur from proximal limb trauma such as open fractures; traumatic amputations such as forequarter

FIGURE 26.1. A: Application of pelvic sheet to provide external stability and reduce pelvic volume. B: Pelvic sheet in place swaddling patient’s pelvis with application of pressure over both iliac wings and trochanteric area. The clamps are applied as cephalad, caudal, and lateral as possible to prevent obfuscation of subsequent imaging. Should groin access be necessary, the sheet may be fenestrated without significant compromise of the pelvic binding ability.

amputations; and closed disruptive injuries such as scapulothoracic dissociation.²¹ Because bleeding commonly comes from arterial sources, emergent embolization following attempts at closed injury reduction and application of nonconstrictive compression dressings will frequently significantly reduce further blood loss. However, emergent operative intervention to control bleeding may have to be considered, especially in the presence of proximal limb or forequarter amputations.¹⁴ Scapulothoracic dissociation injuries can be commonly identified on chest radiographs but may elude casual observation due to postinjury reduction. A combination of arterial injuries with venous bleeding in addition to brachial plexus disruption may pose a significant source of hemorrhage. If technically feasible, application of a chest-arm compressive spica dressing may limit fluid extravasation into the soft tissue planes of the torso. Should these measures prove unsuccessful, interventional angiography can prevent ongoing arterial bleeding. Surgical exploration of the injured shoulder girdle in a patient with known scapulothoracic dissociation is prone to significant hemorrhage in the acute setting and is not advisable.^{12,13}

Spine Injuries

Life-threatening conditions may arise from several types of spinal column injuries. Upper cervical spinal cord or brainstem injury may be caused by bony or ligamentous disruption from the craniocervical junction through the C4 level. Patients with craniocervical injuries in particular are at risk for anoxia due to loss of respiratory drive secondary to concurrent brainstem or upper cervical cord injury. A particular worry in dealing with all spinal injuries is the potential for “occult” or underdiagnosed extent of spinal trauma, with potential for devastating consequences due to the delay in diagnosis. There are several potential spinal conditions typically overlooked. Spinal dislocations or ligamentous injuries may not be recognized on initial imaging tests because of a partial “rebounding mechanism” leading to a spontaneous, yet inherently unstable, skeletal reduction. Distractive spine injuries are especially worrisome due to their highly unstable nature and high propensity for associated neurovascular injury.²² Other patients affected by critical but often occult or underappreciated spinal injuries are individuals whose

spinal column has been subject to autofusion from a variety of conditions. Patients with ankylosing spondylitis, diffuse idiopathic skeletal hyperostosis (DISH), or high-grade spondylosis challenge clinicians due to their propensity to sustain subtle yet highly unstable injuries in the setting of their underlying complex anatomy. Due to the underlying disease processes, spinal injuries in this setting are more prone to increased bleeding and secondary displacement imposed by cantileverage of the fused spinal column above and below the injury zone.¹⁸ In addition to delayed or secondary spinal cord injury, there have been reports of esophageal disruption or aortic injury as causes of delayed death or major morbidity in patients affected by ankylosing spinal disorders. Any form of distractive spinal injury or fracture in an ankylosing spinal disorder should result in expedient and aggressive immobilization to protect the spinal cord and column. Such temporizing measures can include placement of sandbags around the head and immobilizing the head with tape to provisional application of a halo ring and vest, unless contraindicated. For patients with the more common flexion-type cervical spine injuries, leading to jumped or perched facets or significant malalignment on lateral cervical radiographs, strong consideration should be given to urgent closed skeletal reduction under controlled circumstances. Acute reduction of cervical spine fracture dislocations in an emergency room setting prior to getting a magnetic resonance imaging (MRI) scan has been shown to be a safe and effective intervention for patients with spinal cord injury and may decrease the incidence and severity of secondary pulmonary insufficiency, acute respiratory distress syndrome (ARDS). Cervical traction to accomplish reduction of cervical fractures is the most commonly performed approach. Application of Gardner-Wells head tongs and sequential increase in weight along with intermittent neurologic evaluation is performed in a controlled environment that includes fluoroscopy and automated vital sign monitoring.²² Contraindications to application of Gardner-Wells tongs include the presence of a skull fracture in the area of intended pin application and the presence of distractive-type neck injuries.

Spinal injury with secondary neurogenic shock should also be considered in the differential diagnosis of patients affected by sustained severe hypotension. This condition can result from fracture dislocations of the subaxial cervical spine or the upper thoracic spine with spinal cord injury and direct disruption of sympathetic nerve input (Fig. 26.2). Neurogenic shock

FIGURE 26.2. A: Initial lateral cervical radiograph of a young man after a motorcycle crash. He presented with paraplegia and neurogenic shock. Once the shock was under control, the next phase in care was rapid closed reduction of the cervical spine. B: Postreduction radiograph. Patient went on to definitive surgical stabilization at 48 hours after resuscitation and stabilization.

TABLE 26.1**COMPARISON OF NEUROGENIC AND HEMORRHAGIC SHOCK**

■ PARAMETER	■ HEMORRHAGIC SHOCK	■ NEUROGENIC SHOCK
Blood pressure	↓	↓
Heart rate	↑	↓
Urine output	↓	↔
Skin	Pale, clammy	Warm, pink
Mental status	Anxious	Normal
Central venous pressure	↓	↓

is typically manifested by systemic hypotension with loss of peripheral vascular resistance, normal to increased urine output, a relative bradycardia, and warm, well-perfused extremities (Table 26.1). Protracted efforts at treating this condition with excessive intravascular fluid administration are usually unsuccessful and may lead to fluid overload and cardiopulmonary deterioration. Neurogenic hypotension or shock is preferably treated with intravenous pressors in addition to the judicious fluid resuscitation used to fill primarily dilated venous capacitance vessels. Correcting neurogenic hypotension permits the remainder of the workup to be completed safely, and perfusion and oxygenation of a damaged spinal cord are enhanced. Optimizing perfusion through appropriate resuscitation reduces the potential for enlarging the zone of primary spinal cord injury while enhancing any potential neurologic recovery.²³

Respiratory dysfunction and failure as a result of prolonged supine bed rest in cervical traction or delayed mobilization due to spine trauma in general has been described repeatedly.^{24–26} In addition, emergent surgery for spinal injury is commonly recommended for patients with neural compromise in association with highly unstable injury patterns that are unreducible by closed means.

While type 2 odontoid fractures constitute the most common type of spinal fracture requiring hospitalization in elderly patients, the optimal therapeutic approach remains uncertain. These fractures are frequently unstable and are associated with high mortality rates both in the acute and in the subacute phase of care, apparently irrespective of treatment choice. Similar to femoral neck fractures in the elderly, technical advances in fracture care have seemingly not improved survival rates or functional outcomes at 1 year after injury. Current treatment options range from an all-out aggressive multispecialty effort in patients deemed capable of returning to meaningful function to palliative care in those with poor outcome potential.^{19,27}

Timing of Surgical Intervention

A lack of consensus remains as to the ideal timing of fracture stabilization in the multiply injured patient.⁹ There is little doubt that early definitive skeletal stabilization can reduce secondary “fracture disease,” such as pulmonary decompensation, thromboembolism, decubitus ulcers, and soft tissue compromise in an injured limb. However, untimely and extensive early surgical procedures may also aggravate pulmonary injury and dysfunction if the invasiveness of fracture stabilization surgery incurs hypovolemia and necessitates major fluid resuscitation.²¹ Any secondary perioperative hypotension may also aggravate central nervous system and spinal cord injury as

a major “second hit” phenomenon. In general, however, every reasonable attempt should be made to provide surgical débridement and some form of stabilization to high-grade open long bone and joint injuries.^{28–30} Temporary stabilization of the pelvic ring—as outlined earlier in this chapter—can be a major resuscitation aid in an “open-book-type” pelvic ring injury.¹⁶ And, specifically, stabilization of femoral shaft fractures within 24 hours specifically has been shown to reduce the rate of ARDS.³¹

The success of treatment of open fractures is closely related to the severity of soft tissue injury and the amount of primary bone loss. Limiting the timing to surgical débridement to within 8 hours has been proposed as a key variable to reduce the risk of osteomyelitis and delayed fracture union in tibial fractures in the past. However, the evolving current opinion is that the quality of the débridement is likely of far greater importance than compliance to a specific time frame for débridement.³² Similarly, timing of thoracolumbar surgery for stabilization of acute fractures with or without spinal cord injury has been the subject of long-standing divergent opinions, with the definition of “early” still being subject to debate. While undeniably, respiratory distress and pneumonia remain the leading cause of death in spinal cord injury, there is some modest evidence suggesting that early surgery may enhance chances for spinal cord injury recovery or protect the patient from secondary neural injury. Additionally, the ability to mobilize a patient into an upright position early following injury may play an important role in reducing the risk of pulmonary decompensation and nosocomial pneumonia.^{24–26}

In general, early surgical intervention for musculoskeletal trauma should be expedient and effective in stabilization while minimizing extent of surgical exposure, dissection-related blood loss, and anesthetic duration. There is a well-accepted advantage of integrating musculoskeletal trauma care into general trauma care efforts, with optimal communication between services necessary to best suit the care of an individual patient to his or her specific needs.²⁰

LIMB-THREATENING INJURIES

Although the majority of orthopaedic injuries in trauma patients are not life-threatening, they may be a significant source of morbidity.³³ This is particularly true when the injury may directly lead to loss of limb or, if unrecognized or under-treated, result in poor long-term outcomes due to diminished function or chronic pain.³⁴ Injuries in which survival of the limb is immediately threatened include disruption of the major arterial blood supply, due to open fractures, from high-energy or penetrating trauma (Figs. 26.3 and 26.4). Furthermore, any

FIGURE 26.3. External fixation may be thought of as portable traction. This method can rapidly stabilize any extremity and allow for patient mobilization while awaiting definitive internal stabilization.

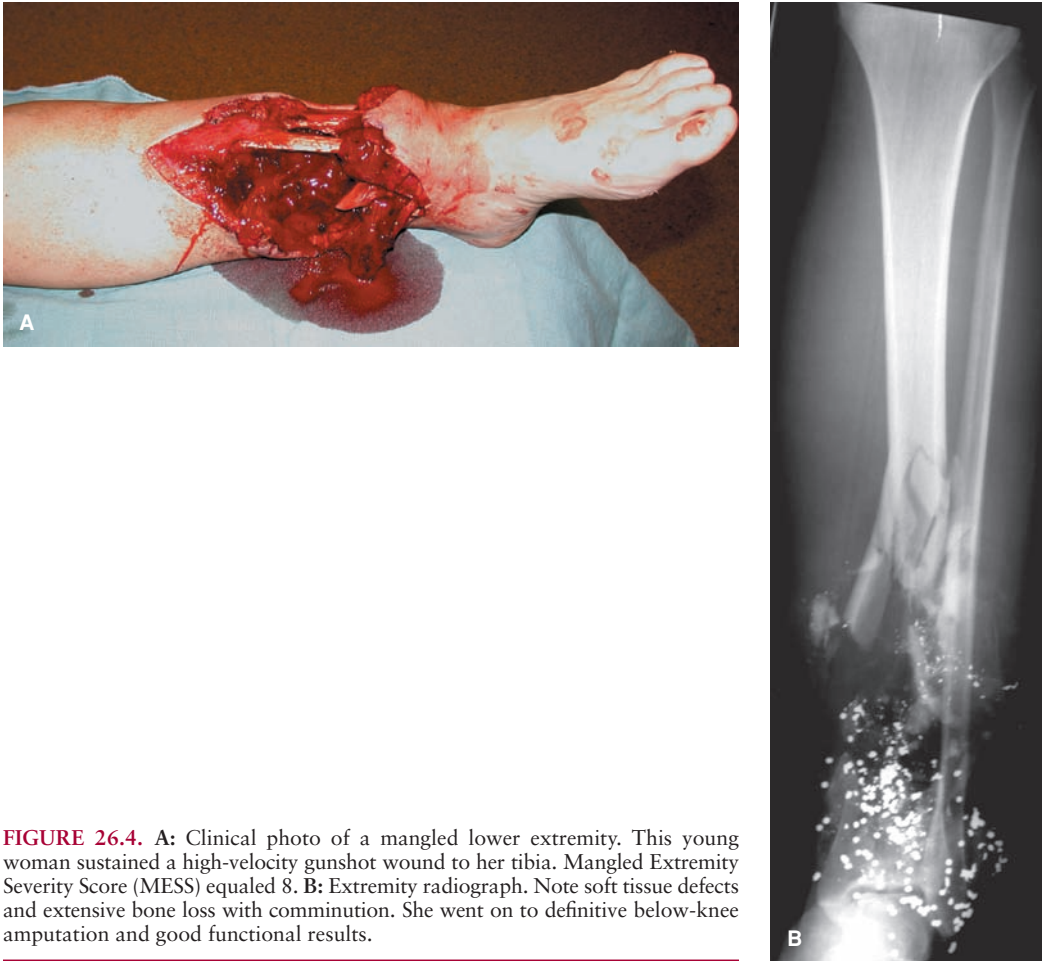

FIGURE 26.4. A: Clinical photo of a mangled lower extremity. This young woman sustained a high-velocity gunshot wound to her tibia. Mangled Extremity Severity Score (MESS) equaled 8. B: Extremity radiograph. Note soft tissue defects and extensive bone loss with comminution. She went on to definitive below-knee amputation and good functional results.

crushing or mangling-type limb injury may result in loss of blood supply on a delayed basis even in the absence of direct arterial injury due to diffuse intimal damage or through subsequent evolution of a compartment syndrome.

Efforts at identifying limb-threatening conditions early with appropriate clinical and radiographic evaluation allows for integration of expedient care for the threatened extremity within the larger treatment needs of the multiply injured patient. Timing of injury care in limb-threatening situations is highly time sensitive, with ischemic limb injuries usually requiring revascularization within 6 to 8 hours and release of symptomatic elevated fascial compartment pressures within a similar time frame.^{35,36} However, distraction prompted by other injuries or impaired cognitive function by the patient may cause considerable delay in caring for a limb at risk. The most effective strategy is implementation of a formal secondary and tertiary trauma survey protocol in all high-risk patients.

Typical clinical signs of limb ischemia consist of disproportionate symptoms of pain and/or tenderness. Important clinical findings, which also require documentation during the initial evaluation, include findings of lacerations, bruising, swelling, and skin discoloration, along with any crepitus or excess tension of the soft tissue envelope on palpation. Finally, functional testing of joints, including range of motion and stability to stress, allows for a more integrated understanding of limb function. When possible, active range of motion with testing of manual resistance motor strength is obtained in nonobtunded patients. Clinical testing of perfusion of a traumatized limb ranges from simple palpation of pulses and assessment of skin color, temperature, capillary refill, and spontaneous blanching to more objective testing such as determining systolic ankle-brachial indices (ABIs), Doppler

duplex evaluation of blood flow, and angiographic contrast studies.^{35–37}

Although limb preservation is generally a preferred treatment goal by far, a timely and well-performed amputation may decrease the injury burden to critically injured patients, decrease acute multiple organ dysfunction, and improve long-term functional outcome. With present medical advances, limb salvage has become increasingly possible technically but at the cost of more surgeries and prolonged invalidity with very doubtful long-term functional gains. In contrast, excellent functional results can be obtained, especially in lower extremity amputations, with state-of-the-art amputee care. Therefore, amputation should not constitute a treatment failure but rather be considered a prudent treatment choice. This decision process is in drastic contrast to loss of limb resulting from an avoidable delay of diagnosis and/or failure to institute timely treatment.³⁸

Vascular Injuries

After realignment of deformed limbs in a trauma patient, any potentially injured limb should have its vascular and neurologic status evaluated. Diagnosis of clinically significant vascular injury may be made by using the systolic ABI and/or confirming such by angiography if indicated. An ABI of greater than 0.9 is considered low risk for arterial injury, and immediate arteriography is not indicated.³⁵ In contrast, delay in the diagnosis of vascular injury following limb trauma with a warm ischemia time of 6 hours or more leads to a markedly increased rate of amputation.³⁷ Extremity trauma typical for an increased risk of vascular injury includes any penetrating

TABLE 26.2**RISK OF VASCULAR INJURY**

■ LOCATION AND TYPE OF INJURY	■ RISK OF VASCULAR INJURY (%)
Proximal humerus fracture (open or closed, high energy)	<1
Femur shaft fracture (closed)	<1
Femur shaft fracture (open)	1.9
Tibia/fibula fracture (closed)	1
Tibia/fibula fracture (open)	10
Supracondylar femur fracture	1–2
Knee dislocation	16–40
Floating knee (ipsilateral femur and tibia fractures)	29

injury, open fracture, or high-energy long bone fracture as evidenced by history or fracture pattern. Certain anatomic locations have a higher prevalence for arterial injury due to direct proximity of bone or vascular tethering to surrounding fascial structures.³⁷ For instance, displaced fractures to the supracondylar femur and proximal humerus, knee dislocations, and scapulothoracic dissociations are all at an inherently greater risk of concurrent vascular injury through either direct laceration or by distractive intimal damage (Table 26.2).

Mangled Extremity

- 3 The descriptive term “mangled extremity” is commonly used to describe a limb injury with combined major soft tissue and high-grade osseous damage, with or without vascular injury, of such magnitude that limb survival is questionable even under the best of circumstances. The diagnosis of a mangled extremity is usually readily made by the dramatic nature of its clinical presentation. Feasibility of functional limb salvage, however, is far more difficult to ascertain in the acute setting and requires the ability to make difficult decisive treatment decisions with limited information. To aid in the decision-making process, several scoring systems have been proposed to help clinicians systematically review factors that play an important role in predicting outcomes. The most widely used of these scoring systems is the Mangled Extremity Severity Score (MESS; Tables 26.3 and 26.4).³⁹

When the MESS is calculated to be greater than 7, consideration for primary amputation has been recommended. Attempts to salvage limbs with prolonged warm ischemia time, massive soft tissue contamination, neurologic injury, and skeletal instability may lead to not only increased morbidity but also overwhelming sepsis and death. Even if limb salvage has been successfully accomplished, long-term quality of life and functional outcomes scores have called into question the benefit to the patient of reconstructing highly traumatized limbs.³⁸

Additional critical factors to consider before embarking on the reconstruction of a severely injured lower extremity are age, injury load on the patient, presence of comorbidities, severity of soft tissue injury and type of contamination, time to débridement, warm ischemia time, and integrity of neurologic function. In the lower extremity, the presence of severe ipsilateral foot trauma has been associated with extremely unsatisfactory functional outcomes and thus should sway the treating surgeon toward primary amputation.⁴⁰ Similarly, disruption of lower extremity nerves below the knee level with loss of protective sensation, primarily on the foot, usually indicates a

TABLE 26.3**MANGLED EXTREMITY SEVERITY SCORE (MESS)**

■ PARAMETER	■ POINTS ^a
SKELETAL/SOFT TISSUE INJURY	
Low energy (stab, simple fracture, civilian GSW)	1

poor outlook for most patients, regardless of reconstruction method.⁴¹

Diagnosis of neurologic injury in the extremity is often difficult in a multiply injured patient, and it may elude even the most thorough physical examination if the patient has an impaired cognitive status. Unfortunately, even advanced imaging studies such as MRI or electrophysiologic studies rarely provide accurate diagnostic data in the acute trauma setting. Specifically, electromyography would not be expected to show signs of neurologic injury until 3 weeks after injury. Therefore, a thorough clinical evaluation and/or direct surgical exploration of neural elements in case of surgical exposure of an affected nerve can be all the decision-making help that a treating physician may have. In contrast to the upper extremity,

TABLE 26.4**MANGLED EXTREMITY SCORING SYSTEMS**

■ AUTHOR, YEAR	■ SCORING SYSTEM
Johansen et al., 1990 (MESS)	Mangled Extremity Severity Score
Howe et al., 1987	Predictive Salvage Index (PSI)
Russell et al., 1991	Limb Salvage Index (LSI)
McNamara et al., 1994	Nerve Injury, Ischemia, Soft Tissue Injury, Skeletal Injury, Shock, and Age Score (NISSA)
Tscherne et al., 1982 (HFS-97)	Hannover Fracture Scale-97

where repair of transected or avulsed neural elements has a reasonable chance of recovery, in the lower extremity this has been associated with significantly less-satisfactory rates of neurologic recovery and is rarely indicated. Therefore, in general, the boundaries of replantation or limb salvage attempts have a higher propensity toward the acceptable outcome in upper extremity trauma in contrast to severe injury in the lower extremities.

Compartment Syndrome

- 4** Compartment syndromes are defined as a mismatch between tissue perfusion and tissue oxygen requirements secondary to elevation of interstitial tissue perfusion pressure in an anatomically confined space. The most common site for compartment syndromes is the lower leg, with the posterior superficial and anterior compartments being most commonly affected. Other locations include the thigh, foot, and forearm. On occasion a compartment syndrome can also arise in the gluteal and psoas compartments. Pain medication, multiple injuries, impaired cognitive function, and bulky splints hinder accurate physical examination and thus prevent or delay detection of this condition. The earliest and most relevant warning sign of an evolving compartmental syndrome is pain out of proportion to that which is expected with passive stretch maneuvers of the muscles of the fascial compartment.⁴² Other signs such as tension and local tenderness of the fascial compartment are variable and clinically not apparent in the thigh and gluteal region. Pallor, pulselessness, or neurologic signs such as paresthesia or weakness are ominous late signs of compartment syndrome and indicate prolonged ischemia in most circumstances. In patients for whom compliance with physical examination is diminished, a high degree of suspicion and vigilant monitoring is required. Invasive monitoring of intracompartmental pressures may provide information critical to surgical decision making if clinical examination is unobtainable, unreliable, or equivocal. The perfusion gradient (diastolic blood pressure minus compartmental pressure) in the monitored compartment should be greater than 30 mm Hg. If the perfusion gradient falls below 30 mm Hg, then the compartment is at a considerably elevated risk for ischemia and fasciotomy should be considered. The definitive treatment of pathologically elevated compartment pressure consists of a decompressive fasciotomy performed in a timely fashion. Presently, there are no fixed time guidelines regarding decompression of an evolving compartment syndrome. Depending on the affected anatomic region and a number of other variables, decompression within 6 hours from the time of insult is recommended for preservation of tissue.^{43,44} Routine fasciotomies should also be considered after revascularization of a specific extremity or following other reperfusion conditions after a prolonged period of hypotension.^{26–28}

Infection

There are multiple causes for posttraumatic infection. Aside from primary inoculation at the site of injury, the most common cause of infection in a trauma situation is presence of devitalized tissue. Adequate resuscitation efforts with maintenance of oxygenation and tissue perfusion pressures and judicious surgical débridement are important key steps in preventing musculoskeletal infection. Aside from host factors, effective early skeletal stabilization in combination with meaningful surgical débridement and supplemental antibiotic prophylaxis can decrease the likelihood of musculoskeletal infection. From an orthopaedic perspective, the expedient initial skeletal stabilization in an acutely injured patient is the most important adjuvant to decreasing the injury burden of a multiply injured patient. Specifically, intramedullary nails and

temporary external fixation can expedite stabilization to permit improved mobility and care of patients with serious extremity trauma. Similar to the injured abdomen, the role of damage control surgery in orthopaedics, with limitation to only the most critical injuries and in an expedited approach, has become a popular concept and appears to be life and organ sparing in many cases; however, it remains subject to further validation.

INJURIES ASSOCIATED WITH LONG-TERM MORBIDITY

Certain injuries of the musculoskeletal system are associated with increased long-term morbidity if not treated expeditiously. Though not life threatening or limb threatening, these injuries may represent a considerable source of long-term daily disability for the traumatized patient after many of the most severe injuries have healed. Major joint dislocations such as of the hip, femoral neck fractures, open fractures with contamination, talar neck fractures with displacement or dislocation, and thoracic fracture dislocations are examples of injuries with potential significant long-term disability and negative illness impact.

Hip dislocations can be identified on the initial anteroposterior pelvic trauma screening radiograph recommended by the Advanced Trauma Life Support (ATLS) protocol. For dislocations of the hip or fractures surrounding the femoral head and neck, early reduction and stabilization are desirable. Hip dislocations specifically should be viewed with urgency. Earliest feasible closed reduction followed by CT scan is a widely accepted standard of care. Vascular supply to the femoral head is tenuous and is derived largely from the vessels that reach the head after branching from the medial femoral circumflex artery. These vessels then travel through the posterior lateral aspect of the hip joint capsule as the posterior superior retinacular arteries. Prolonged dislocation of the femoral head leads to disruption of these retinacular arteries and may give rise to avascular necrosis (AVN) of the femoral head.^{45,46} Anterior hip dislocations, though much less common, may lead to occlusion of the femoral artery with prolonged pressure from the displaced femoral head. Delay in reduction of this major joint dislocation also makes reduction progressively harder because of spasm-induced muscular contractions. CT of the pelvis following closed reduction of the hip is required to assess for articular debris. Presence of debris within the weight-bearing portion of the hip may lead to accelerated cartilage wear and arthrosis and should prompt consideration for early joint débridement through a suitable arthrotomy. Larger acetabular fragments may require stabilization through internal fixation to ensure congruent joint alignment.

Femoral neck fractures compromise perfusion of the femoral head by virtue of disruption of both vascular supply and outflow.^{45,46} Early stable internal fixation with anatomic reduction and release of an intracapsular hematoma is associated with decreased incidence of AVN or nonunion of femoral neck fractures. Particularly in younger patients, few satisfactory reconstructive surgery options exist for either scenario. While for elderly patients primary hemiarthroplasty or immediate total hip arthroplasty has become the standard of care, posttraumatic hip arthroplasty in younger patients rarely provides a lasting treatment option.^{45–47}

In general, any open fracture, regardless of contamination, requires formal débridement and irrigation. Removal of all foreign material and devitalized tissue at the earliest possible time has been shown to decrease the overall infection rate, both for acute wound infection and chronic osteomyelitis.^{28–30} If the patient is too ill to have adequate débridement in an operating room environment, it should be done as thoroughly as possible in the resuscitation or intensive care arena. Internal

fixation of fractures can then be safely performed after appropriate soft tissue management has occurred, which can also ultimately aid soft tissue healing.^{29,30}

Displaced fractures of the talar neck with or without dislocation of the talar body are associated with a poor prognosis. Urgent reduction of the fracture or dislocation should be undertaken as soon as the diagnosis is made. If skin viability is compromised by underlying bone fragments and is not improved by closed reduction, immediate open reduction and fixation should occur. Although the presence of a talar neck fracture has been considered an indication for urgent operative reduction and stabilization in the past due to the potential for AVN, more recent studies have indicated that emergent surgical intervention may not affect the incidence of AVN. Operative débridement of open wounds and internal fixation of these injuries should be performed at the earliest reasonable time.^{48–50} Delay of reduction of peritalar fractures or dislocations can be expected to lead to soft tissue breakdown, greatly increasing subsequent reconstruction challenges. Neglect of these fractures is associated with a higher incidence of AVN of the talus, subsequent severe arthrosis, and long-term disability.

Neurologic Injury

The presence of a neurologic deficit can be a major source of poor outcomes. Annually, there are approximately 11,000 new spinal cord injuries in the United States. While life expectancy of patients following thoracolumbar spinal cord injury and even higher levels of quadriplegia approximates that of their respective age cohorts, this injury entity still lacks an evidence-based proven treatment of choice. On the whole, no other condition affects patient outcome as profoundly as spinal cord injury. At present, spinal cord injury therapeutic protocols follow four basic philosophies: (a) minimize the occurrence of preventable spinal cord injuries through education of the population at large and high-risk target groups specifically; (b) avoid secondary spinal cord injury or progression of injury through minimizing the occurrence of missed spinal column injuries; (c) optimize chances for spinal cord recovery through a number of measures including adequate resuscitation, timely decompression and stabilization of the spine, and pharmacologic measures aimed at reduction of swelling of neural membranes; and (d) implement a formal spinal cord rehabilitation program at the earliest possible time.⁵¹ Highly publicized reports on breakthrough successes of treatment, including systemic hypothermia or stem cell therapies, are currently based more on opportunistic media reporting rather than objective medical evidence.⁵²

Recovery from spinal cord injury is a highly variable and somewhat unpredictable occurrence. Injury mechanism, age, and health of the patient are major factors influencing the outcomes of spinal cord injury. To date there are no reproducible methods to achieve spinal cord regeneration. Pharmacologic treatment with methylprednisolone had been a widely followed practice in North America after several prominent studies. However, its ongoing routine use has become increasingly controversial due to questions about the study methodology and potential for serious adverse effects of treatment.^{53,54} More than a decade after its widespread implementation, it has become apparent that the recommended high-dose intravenous application of 30 mg/kg methylprednisolone bolus given over 1 hour followed by a drip of 5.4 mg/kg per hour over 23 hours has not produced the anticipated dramatic change in the fate of most spinal cord injury patients. The administration of intravenous methylprednisolone has become a treatment option rather than a standard of care.⁵⁴ Unfortunately, for the foreseeable future there are no medical or cellular treatment regimens for spinal cord injury available outside of controlled clinical trials.

SUMMARY

The diagnosis and management of musculoskeletal injuries in the multiply injured patient population are often complex. Early recognition of injuries leads to diminished morbidity (both early and long term), earlier stabilization of patient hemodynamics, decreased length of stay in the intensive care setting, decreased rates of transfusion, earlier patient mobilization, and decreased mortality.⁵⁵ Improved understanding of how each organ injury complex of multisystem trauma impacts overall patient well-being will improve patient outcomes through enhanced, appropriate collaborative care and communication by the many specialists needed for an optimal outcome. While orthopaedic consultation may be readily available at major level I trauma centers, this is an increasing challenge in the greater community. Similarly, there is a significant trend toward improved survival in multiply injured patients and patients with concurrent thoracolumbar injuries when care is provided at level I centers. Overall, the orthopaedist treating multisystem trauma must understand the basics of general surgery trauma care, and the trauma surgeon needs to recognize, stabilize, and involve the orthopaedic surgeon early in the case of musculoskeletal trauma to optimize appropriate management and minimize morbidity and mortality.

CHAPTER 27 ■ PEDIATRIC TRAUMA

MARY E. FALLAT

KEY POINTS

- 1 Injury is the leading cause of death in children under 14 years of age and prevention, utilizing a public health model, is the most effective method to reduce deaths in children.
- 2 Community hospitals that stabilize injured children prior to transport to trauma centers commonly obtain unnecessary computed tomography imaging first and many of these children later require duplicate scans of the same anatomic region for various reasons, exposing the child to additional inappropriate risk and cost.
- 3 The injured child requires a patient- and family-centered approach to care. Increasingly, family members should be permitted during all phases of resuscitation and care.
- 4 The upper cervical spine is at increased risk for injury in the child because of a larger relative head mass and underdeveloped ligaments, and diagnosis is more challenging due to normal anatomic variants.
- 5 Plasticity of the thorax and transmission of kinetic energy to the lung make parenchymal injury such as pulmonary contusion more common and bony injury such as rib fractures less common.
- 6 Abdominal solid organ injury is unlikely to require surgery.
- 7 Hollow viscus injury is difficult to diagnose and requires a high index of suspicion, serial abdominal examinations, and select diagnostic studies, particularly with patterns of injury such as a “lap belt” contusion.
- 8 Children with unusual patterns of injury including retinal hemorrhages, multiple subdural hematomas without skull fracture, genital or perianal injury, burns in unusual places, and multiple new and old fractures mandate evaluation for inflicted trauma.
- 9 Although the child may have a higher survival rate following traumatic brain injury (TBI), the long-term negative impact of a minor TBI on learning and personal quality of life is much greater.
- 10 Children are emotionally vulnerable and follow-up should provide support to recognize and care for posttraumatic stress disorder in this population.
- 11 The Emergency Medical Services for Children (EMSC) program emphasizes a step-by-step approach to injury prevention by establishing goals and objectives with measurable outcomes.

EPIDEMIOLOGY

- 1 Unintentional injury is the leading cause of death among children ages 14 years and under in the United States and remains

the greatest public health problem affecting young people.¹ Despite the fact that death and disability resulting from trauma surpass all major diseases in young Americans, far more federal funding is spent each year to reduce the incidence

of cancer, stroke, heart disease, and acquired immunodeficiency syndrome (AIDS) than injury.

Injury prevention is the most effective method of reducing death in children and adolescents.² The science of injury prevention is complex and involves societal decisions that trade safety for other benefits. For example, individual states have chosen both to raise the speed limit past 55 miles per hour to reduce travel time and to rescind motorcycle helmet laws to preserve individual freedom, rather than to protect the populace from increased death and disability due to vehicular crashes.² Health care workers can ultimately play a pivotal role in injury prevention by carefully documenting and collecting data regarding how injuries occur, which will serve dual roles of identifying populations at risk and providing compelling evidence to lawmakers in support of effective injury prevention legislation.

Trauma registries are one way to show trends or patterns of specific injuries and to use cumulative data to build a case for legislation. The National Pediatric Trauma Registry (NPTR)³ and the National Trauma Registry of the American College of Surgeons (NTRACS)⁴ are examples of national registries that have identified and can elucidate areas to target for prevention initiatives. The predominant mechanism of injury varies by age, with inflicted injuries most common in infants, falls more common in young children, pedestrian injuries in toddlers and elementary school-age children, and motor vehicle trauma in adolescents. Disparities in clinical and functional outcome have also been identified using registry data, providing opportunities for targeted initiatives. For example, worse outcome at discharge has been documented in black children after traumatic brain injury (TBI) compared with equivalently injured white children.^{5,6}

Other disparities in pediatric trauma care deserve mention. Mortality rates for all types of trauma are greater in rural parts of the country than in cities and suburbs. The reasons for this are protean and include longer times from injury to definitive care,⁷ in-hospital delays to definitive treatment,⁸ less time for injury prevention education in schools and primary care offices, and socioeconomic and ethnic factors. Other associations have been identified that increase susceptibility to trauma. Children with behavioral disorders such as attention-deficit hyperactivity disorder (ADHD) have one and one-half times the odds of sustaining a variety of injuries from multiple causes than those without behavioral disorders, even after controlling for known demographic correlates.⁹ Sometimes age works in favor of youth, with less morbidity after high-level falls in those 14 years of age and younger.¹⁰

The “trimodal” mortality curve described in adults is not seen in children. Children who die from injury do so either at the scene or within a few hours of hospital admission. Late deaths due to sepsis or organ failure are rare.¹¹ After injury control, prompt recognition and emergent treatment of life-threatening injuries are the most important ways to decrease death and disability caused by pediatric trauma. Whether or not outcome for a pediatric trauma victim is affected if care is rendered at a children’s versus adult trauma center remains a somewhat controversial and unanswered question.¹²

PREHOSPITAL CARE

Pediatric runs represent approximately 10% of all prehospital emergency calls in the United States. Although educational courses such as Pediatric Education for the Prehospital Professional (PEPP)¹³ and Pediatric Advanced Life Support (PALS)¹⁴ have augmented the knowledge base of some prehospital providers, the recommended amount of pediatric training included in the U.S. Department of Transportation National Highway Traffic Safety Administration Emergency Medical Technician-Paramedic National Standard Curriculum is temporally limited and basic. The adequacy of prehospital airway management and the ability to obtain venous access in chil-

dren by individual providers are associated with proper training, experience, skill maintenance, and online and offline medical oversight for prehospital care services.^{15,16}

A goal of pediatric prehospital care is to prevent secondary brain injury associated with hypoxia or hypotension by controlling the airway and striving for normocapnia and normotension with appropriate fluid resuscitation. All ambulances must be equipped with pediatric equipment in various sizes, including blood pressure cuffs, masks, endotracheal tubes, and intravenous (IV) access devices.¹⁷ Prehospital care of injured pediatric patients for short transports may be limited to maintaining spinal precautions, assurance of an adequate airway, administration of oxygen, and rapid transport to definitive care. Placement of a definitive airway and establishment of IV or intraosseous (IO) access is recommended for longer transport times.

An inclusive trauma system must provide for the needs of injured children as well as adults, with triage by the prehospital provider to the closest appropriate facility with the capabilities of caring for major trauma. This may be a free-standing pediatric trauma center or a regional trauma center with a verified pediatric component.¹⁸ The receiving center must have the necessary personnel and equipment to care for the injured child, as outlined in *Resources for Optimal Care of the Injured Patient: 2006* by the American College of Surgeons Committee on Trauma.¹⁹ Despite evidence for improved outcomes of severely injured children admitted to high-level trauma centers, almost one third of children with severe TBI fail to receive care in such centers and regionalization efforts in many parts of the country are still in their infancy.²⁰

INITIAL RESUSCITATION AND EVALUATION

Preparation is the key to a successful pediatric trauma resuscitation. In institutions using a team approach, interventions may be done simultaneously (i.e., for airway and circulation).

The best protection for the airway in the child who is breathing spontaneously is maintenance of a superior and anterior position of the midface (sniffing position), while keeping the cervical spine immobilized. If the airway is inadequate, it can be opened with a gentle jaw thrust. The mouth is cleared of blood and foreign material and supplemental oxygen is used. In a young child, respiratory compromise can result from gastric dilatation or from compression of the diaphragm by intra-abdominal blood or air, necessitating the use of a gastric tube. The tube should be inserted orally if there is concern for a basilar skull or midface fracture.

Children with obvious respiratory distress, those with a Glasgow Coma Scale (GCS) score of less than or equal to 8, or those who arrive in shock must have immediate tracheal intubation. The proper-size endotracheal tube can be estimated by choosing one that corresponds to the diameter of the child’s small finger or the external nares or using an appropriate reference as a guide. An excellent approach is the use of color-coded drawers containing all of the equipment necessary for a certain-size child and using a length-based pediatric resuscitation tape to estimate the child’s weight.²¹ In children younger than 8 years, nasotracheal intubation is avoided because of the more anterior and cephalad positioned airway, relatively large adenoids and tonsils, a soft short trachea, and the potentially serious complications associated with blind nasal passage. After preoxygenation, a pharmacologically assisted intubation using a neuromuscular blocker and a sedative is performed, unless the child has a GCS of 3 or has arrested. A chest radiograph should be obtained to confirm proper position of the endotracheal tube. If the airway cannot be secured by the most senior person in the resuscitation room, a temporizing needle cricothyrotomy is placed and jet insufflation initiated until an

FIGURE 27.1. Child with multiple dog bites on face, extremities, and torso.

airway can be established in the operating room. Tracheostomy in young children is reserved for experienced surgeons under operating room conditions only.

Because of small blood volumes in children, shock can occur rapidly from blood loss from external wounds (Fig. 27.1). Bleeding should be controlled with pressure bandages. Preferred sites for percutaneous IV access in the child are the back of the hand, the antecubital fossa, and the saphenous vein at the ankle. If a child is in shock, and no IV line can be established after two attempts, an IO needle is placed in an uninjured proximal tibia. Alternatively, a percutaneous femoral venous line can be placed by an experienced physician. It is important to follow a protocol so that time is not wasted with too many attempts at percutaneous IV access before resuscitation can begin. Baseline laboratory work can be drawn concurrent with establishing IV access, including a complete blood count (CBC), serum aspartate aminotransferase, and amylase. A urinalysis is done if there is occult blood in a urine dip for blood. A clot to hold or type and cross match is sent to the blood bank as indicated by the physiologic status of the child. An arterial blood gas is sent if the child required tracheal intubation. A prothrombin time (PT) and partial thromboplastin time (PTT) are indicated for a GCS below 13, low systolic blood pressure, open/multiple bony fractures, and major soft tissue wounds.²² There are no routine laboratory tests that have utility as good screening tools for pediatric abdominal trauma.²³

A child's systolic blood pressure should be at least 70 mm Hg plus twice the age in years.¹⁴ In general, a blood pressure of less than 70 mm Hg systolic is considered shock in a child, with the exception of small infants. Hypotension is a late sign of shock because of increased physiologic reserve in children compared with adults. The initial signs of shock can be subtle in a child and manifested only by tachycardia or lethargy. Once hypotension has developed, a child has already lost approximately 40% of the circulating blood volume and traumatic arrest is imminent if treatment is delayed.

Fluid resuscitation begins with 20 mL/kg of warmed isotonic crystalloid given by rapid IV/IO push. This is approximately one fourth of the blood volume of a child. This fluid bolus can be repeated twice, but if the child remains in shock, the source of bleeding should be quickly identified and addressed. Transfusion of O-negative packed red blood cells may be needed at an initial volume of 10 mL/kg. A Foley catheter should be inserted, assuming no blood at the urethral meatus or an unstable pelvic fracture. In addition to reestablishing normotension, a proper response to resuscitation includes slowing of the heart rate, return of extremity skin color and warmth, clearing of the sensorium, and a sustained urine output of 1 to 2 mL/kg per hour.

Small children are especially prone to hypothermia, which may render the child unresponsive to resuscitation efforts. Use of convective air blankets, warm IV fluids, and warm blankets is indicated as soon as feasible.

During the resuscitation, radiographic studies of the chest and pelvis are performed and cervical spine protection is maintained until age-appropriate views can be obtained (anteroposterior, lateral, and odontoid). It is difficult to obtain an open-mouth odontoid view in an infant or young child.²⁴ Clearing of the cervical spine is relatively elective; time should not be wasted on these films if other injuries take priority. In the hemodynamically unstable child, a quick sonographic evaluation of the pericardium and the peritoneum (the focused sonographic assessment for trauma [FAST] examination) for blood can be helpful in establishing the priorities of treatment. Blood in the pericardial or peritoneal cavity in the persistently unstable child demands surgical intervention. In the physiologically normal child, a computed tomography (CT) scan of the abdomen and pelvis with IV contrast is indicated in certain situations (Table 27.1). In this era of increasingly fast and sensitive radiographic testing, the multidetector-row CT has gained popularity, as has the total-body CT. There are three arguments against the routine use of total-body CT in children: (a) the medical radiation burden and increased cancer induction risk, (b) cost-effectiveness, and (c) the risk of pseudodisease with overinterpretation of clinically unimportant findings.²⁵ Community hospitals that stabilize injured children prior to transport to trauma centers commonly obtain CT imaging first. Many of these children later require duplicate scans of the same anatomic region for various reasons (scan inadequate or not sent with the patient, computer software incompatible, hard copies sent with inadequate tissue window images to allow assessment), exposing the child to additional risk and cost.²⁶

TABLE 27.1 INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR COMPUTED TOMOGRAPHY OF THE ABDOMEN AND PELVIS

- History of shock but now stable
- Unexplained drop in hematocrit
- Positive FAST examination
- Presence of hematuria
- Presence of lower rib or pelvic fractures
- Unreliable abdominal examination because of head injury
- Presence of abdominal pain/ecchymosis
- Uncorrected base deficit

FAST, focused sonographic assessment for trauma.

Although ultrasound is reasonably sensitive in detecting the presence of fluid in the abdomen, its accuracy is highly dependent on the operator. Some data suggest that hospital resources are conserved when the FAST examination is incorporated into the algorithm in the evaluation of the pediatric abdomen after blunt trauma.²⁷ Ultrasound, however, may not detect the presence of intraparenchymal solid organ injuries without free blood, may miss small amounts of blood early in the resuscitation, cannot be used to grade the degree of injury to a solid organ, and cannot exclude pancreatic or bowel injury. In addition, the finding of blood in the peritoneum in a stable child does not dictate laparotomy. For all of these reasons, the role of FAST in pediatric trauma patients remains controversial. Neither ultrasound nor CT reliably detects the presence of a bowel injury. Serial abdominal examinations are indicated, and a diagnostic peritoneal lavage (DPL) may occasionally be helpful in determining the need for laparotomy.

Throughout this critical period of resuscitation and evaluation, there are a few additional focused needs of children to consider. One is the management of pain, which is often overlooked, even when pain scale charts or prompts are used.²⁸ Another is the emotional needs of the child. A frightened child is emotionally labile and may regress to infantile behavior. A calm and reassuring approach with attempted explanation of procedures gains the most cooperation. There is evidence that the psychological effects surrounding a traumatic event are long lasting, even if the trauma is relatively minor. The needs of the “injured” family must be met by providing a continual flow of information to the distressed parents or guardian during the resuscitation. A chaplain or member of the family support services staff can admirably serve this vital role on a pediatric trauma team. There is now a body of literature providing advice on “breaking bad news.”^{29–32}

- 3 In addition, with the shift in medical training from disease-centered to patient-centered and family-centered care, there has been increasing interest in and allowance of family presence during invasive procedures and cardiopulmonary resuscitation.^{33,34} Although this concept has had limited exposure in the emergency pediatric trauma setting, family members often desire to be present and are more accepting of death and more satisfied with the level of care that their loved one received if they witness the events of the resuscitation.³⁵ Pediatric health care workers who have more frequent contact with seriously ill children are more likely to accept parental presence.³⁴

MANAGEMENT OF SPECIFIC INJURIES

Neurologic and Extracranial Head Trauma

Traumatic brain injury is the leading cause of traumatic death and disability in children. The annual clinical burden remains high, with 50,658 TBI-associated hospitalizations in 2000 and a corresponding financial burden of \$1 billion.³⁶ Unfortunately, the majority of the proinflammatory response caused by TBI occurs within 6 hours of injury, making early treatment initiatives challenging. Multiple pathways contribute to the endpoint of hypoxic ischemic injury, and a host of clinical trials evaluating single-modality translational treatment strategies have yielded uniformly disappointing results with no intervention resulting in improved outcome.³⁷ The National Institutes of Health (NIH) is currently promoting prospectively designed studies that will employ multiple therapeutic agents in combination. Emerging strategies that may be considered include hypertonic saline resuscitation, hypothermia, and cellular therapeutics (bone marrow progenitor cell therapy).³⁸ Each has its own inherent benefits, risks, and complications, and hypertonic saline and hypothermia ideally need to be started very soon after injury. Most treatments for TBI are

designed to mitigate the secondary effects of the initial injury. Progenitor cell therapy explores the potential of reparative treatments and involves harvesting bone marrow from patients with severe TBI within a few days of injury, separating the cells, and reinfusing progenitor cells.

Treatment guidelines for the acute prehospital and the acute medical management of severe TBI in infants, children, and adolescents have been published, with the goal of assimilating the data that exist and presenting them within an evidence-based framework.^{39,40} The methodology revealed a significant dependence on information derived from the adult population or personal experience due to a paucity of high-quality clinical trials in brain-injured children, thus limiting the strength of the recommendations. However, there is some evidence that pediatric patients with severe TBI should be treated in a pediatric trauma center rather than an adult trauma center and that organized systems of trauma care result in an overall reduction in the mortality rate for individuals with severe TBI.¹² The following represent reasonable initiatives or strategies based on the clinical evidence that exists.

Primary treatment of a child with a TBI preferably begins at the scene of the injury with correction of hypoxemia and shock by restoring oxygenation, ventilation, and perfusion. Supplemental oxygen should be administered. There is no evidence to support an advantage of endotracheal intubation (ETI) over bag valve mask (BVM) ventilation for the prehospital management of the airway in children with TBI who have short transport times to the hospital.⁴¹ If prehospital ETI is instituted for pediatric TBI patients, specialized training and use of end-tidal CO₂ detectors is considered necessary. The airway should be secured in patients who have severe head injury (GCS <9), the inability to maintain an adequate airway, or hypoxemia not corrected by supplemental oxygen. Hypocarbica (partial pressure of arterial carbon dioxide [PaCO₂] <30 to 35), due to excessive ventilation in an emergent situation from large manual tidal volumes and rates, correlates directly with decreased functional outcomes from TBI and must be avoided. Hypotension should be identified and corrected as rapidly as possible with fluid resuscitation. Hypotension is defined as systolic blood pressure below the fifth percentile for age or by clinical signs of shock. The lower limit of systolic blood pressure (fifth percentile) for age may be estimated by the following formula: 70 mm Hg + (2 × age in years).¹⁴ A retrospective study evaluating the temporal relationship of hypotension to severe TBI found that a poor discharge Glasgow Outcome Score was predicted by hypotension occurring during the first 6 hours after injury.⁴²

A thorough neurologic examination is performed and documented, including the GCS score. The verbal portion of the score has several adaptations for application in infants and toddlers (Table 27.2), but it is the motor score that correlates

TABLE 27.2 CLASSIFICATION

FIGURE 27.2. A: Scalp wound with underlying open frontal skull fracture. B: Bone window computed tomography image showing comminuted frontal skull fracture, pneumocephaly, and multiple additional skull fractures. C: A small frontal contusion is seen beneath the skull fracture.

best with outcome. Except for the most minor cases, a head CT scan is performed in all children with evidence of neurologic injury (Fig. 27.2). For those with severe TBI, serial scans ordered for increased ICP and neurologic deterioration best correlate with the need for operative intervention.⁴³

Secondary measures to treat TBI in children include evacuation of an intracranial space-occupying hematoma, normalization of intracranial pressure (ICP), maintenance of tissue oxygenation, external ventricular drainage, and decompressive craniectomy in rare cases of conservative treatment failure.^{44,45} Although mass lesions from hemorrhage requiring surgical intervention are relatively uncommon in children, cerebral edema is common and deserves treatment. Children with a GCS score of 8 or less and those with evidence of cerebral edema on CT scan are best managed with sedation, paralysis, endotracheal intubation, and mechanical ventilation to keep the PaCO₂ at approximately 35 mm Hg. Prophylactic hyperventilation has the potential to reduce cerebral blood flow to damaged or marginal brain tissue to ischemic levels. In a retrospective cohort analysis of significant pediatric TBI done after publication of the 2003 acute TBI medical manage-

ment guidelines, the incidence of severe hypocarbia decreased but remained relatively high and predicted mortality.⁴⁶

Evidence exists showing poorer outcomes with sustained ICP greater than 20 mm Hg, making ICP-guided therapy potentially beneficial.⁴⁷ For example, an ICP transducer (or ventriculostomy catheter) can be placed (with the exception of young infants with open cranial sutures) and therapy targeted to maintain ICP less than 20 mm Hg and a cerebral perfusion pressure of at least 40 to 65 mm Hg. Hyperosmolar therapy with either mannitol or hypertonic saline is an effective first-line option for controlling ICP. However, mannitol leads to a significant diuresis and potential subsequent volume requirement. Brain metabolism is minimized by treating fever and avoiding seizures. The use of anticonvulsants early may be associated with reduced mortality.⁴⁸ The occurrence of posttraumatic seizures and epilepsy increases with injury severity, younger age, and longer follow-up duration, and both are associated with adverse outcome.⁴⁹ Despite aggressive treatment, the overall mortality rate from severe head injury in pediatric patients is approximately 8%, and the coexistence of extracranial injury significantly reduces recovery potential.⁵⁰

The significant reported variation in the use of paralytic agents, seizure medications, induced hypothermia, and intracranial pressure monitoring across pediatric critical care units suggests that standardized treatment protocols should be implemented so that more meaningful data can be accrued.^{48,51} Other authors have enunciated the importance of establishing age-dependent guidelines that cover the spectrum of TBI management and recovery of function.⁵²

Jankowitz and Adelson⁵³ describe five key areas for prioritization and future research in pediatric TBI: (a) prevention, including educational programs in combination with mandatory interventions or laws that are directed at sports programs, recreational activities, and vehicular modifications; (b) development, assessment, and implementation of a standard initial assessment tool to accurately define the severity of TBI and facilitate management; (c) use of multimodality, monitor-guided therapy; (d) implementation of an algorithm that standardizes anatomic and functional imaging at designated intervals to provide meaningful data; and (e) development of pediatric-specific TBI outcome measures.

Spinal Trauma

The incidence of pediatric spine injuries has been reported as 2% to 5% of all spine injuries.^{54,55} Spinal trauma is frequently associated with concomitant system injuries including head, abdominal, and thoracic injuries and long bone fractures.⁵⁶ Head injury is the most common injury associated with spinal trauma. Any patient suspected of having a spinal injury must be immobilized until the entire vertebral column and spinal cord have been assessed. Spine injuries after minor trauma in children are less common than in adults because of the greater mobility and elasticity of the pediatric spine and a smaller body mass. However, the ligamentous laxity and increased mobility in the immature spine may predispose to lethal distraction injuries during forceful trauma.⁵⁷ Spinal trauma may occur with or without spinal cord injury (SCI). The mechanisms of SCI can be broadly classified as axial loading, dislocation, lateral bending, rotation, and hyperflexion/hyperextension. Severe injuries often result from a combination of these.⁵⁸ The CT scan is the best test to evaluate persistent symptoms or abnormalities seen on plain film, but it is not required as often as it is performed and poses a radiation risk. A CT "topogram" or scout film may be helpful to localize areas that need to be scanned.²⁴ The use of an algorithm to determine which patients need plain films and which patients need more thorough evaluation may be helpful.^{59,60} Magnetic resonance imaging (MRI) should be performed to evaluate for clinical signs or symptoms of SCI.⁵⁸

4 Certain anatomic features predispose younger children (age younger than 8 years) to injury of the upper cervical spine, from the occiput to C3.⁶¹ These include a proportionately heavier head and weaker ligaments that permit greater mobility of C1 on C2 compared with the lower spine; horizontally inclined articulating facets and immature vertebral joints that facilitate sliding; growth centers that are susceptible to shear forces during rapid deceleration or hyperflexion-extension; and a higher fulcrum of flexion.⁶¹ The fulcrum of cervical movement is located higher in young children (C2-3) compared to adolescents and adults (C5-6). In children older than 8 years, cervical spine fractures are primarily seen caudal to C4.⁶¹ As a result of the anatomic and biomechanical differences between the immature pediatric spine and the mature adult spine, 60% to 80% of all pediatric vertebral injuries occur in the cervical region.⁵⁸

Some normal anatomic variables make interpretation of cervical spine films in children challenging and misdiagnosis or misinterpretation common.^{61,62} Pseudosubluxation occurs normally in approximately 19% to 40% of children and is most commonly seen as anterior displacement of C2 on C3 but

can also be seen at the C3-4 level.⁶¹ An increased distance between the dens and the anterior arch of C1 may also occur without any pathologic consequences. Skeletal growth centers may resemble fractures, especially involving the odontoid and the spinous processes. If there is doubt over whether an abnormality exists, it is wise to protect the spine until expert consultation can be arranged.

An abnormality seen more commonly in children is spinal cord injury without radiographic abnormality (SCI-WORA).^{61,63} This phenomenon is attributed to the elastic nature of the child's spine and may result from longitudinal distraction, hyperflexion, hyperextension, or spinal cord ischemia. The five specific SCI clinical syndromes that have been described in SCIWORA are the central cord syndrome, Brown-Sequard syndrome, anterior spinal artery syndrome, partial SCI, and complete SCI.⁵⁸ The diagnosis is established by MRI, and prognosis for recovery after a complete SCI may be poorer than after a SCI associated with a fracture.⁵⁷

Thoracic and lumbar spine injuries including multilevel injuries are more common in children older than 9 years. The most common mechanisms of injury are motor vehicle crashes and sports-related activities. Although most patients with thoracolumbar spinal trauma can be treated conservatively, indications for surgery include persistent instability, significant compression fracture of the vertebral body, spinal kyphotic deformity of more than 20 degrees, vertebral dislocation, and spinal cord compression associated with progressive neurologic symptoms.⁵⁶ Some pediatric patients with devastating spinal cord injuries can recover substantial neurologic function. High-dose steroid therapy for spinal cord injury is controversial.⁶⁴⁻⁶⁶

Thoracic Trauma

Thoracic trauma is seen in 4% to 6% of children presenting to pediatric trauma centers and rarely occurs in isolation.⁶⁷ Mortality risk is increased due to associated injuries, particularly TBI.

There are important anatomic and physiologic differences between children and adults who present with thoracic injury. 5 Rib fractures are uncommon in children because the chest wall is more compliant. Displaced rib fractures can occasionally cause thoracic or abdominal injury, and multiple rib fractures are associated with increased morbidity and mortality. Posterior rib fractures in infants have a high association with inflicted trauma. Aortic and great vessel injuries are uncommon because of greater vessel elasticity and mobility of mediastinal structures. Enhanced pulmonary vasoconstriction results in less bleeding.

The most common injuries in children are pulmonary contusion, hemothorax, and pneumothorax. Pulmonary parenchymal injury following blunt trauma may result from direct compression, shearing forces, contrecoup compression, or laceration from fractured ribs. Chest radiography is the primary screening modality for thoracic injury, both to identify life-threatening injuries and to locate tubes and catheters (Fig. 27.3). Pulmonary contusion is characterized by areas of alveolar and interstitial hemorrhage and edema that appear as ill-defined opacities that do not follow anatomic boundaries.⁶⁸ Secondary edema from disruption of the alveolar-capillary interface peaks at 24 to 36 hours following injury, and the radiographic appearance of the lungs may worsen over the first several days. Pneumothorax and pneumomediastinum most commonly occur following alveolar or small airway rupture. Air dissects medially along peribronchial tissues toward the mediastinum or pleural space. If the air dissection is extensive, increased air pressure shifts the flexible mediastinum, compressing the contralateral lung and twisting the great vessels (tension pneumothorax).⁶⁸ If this condition is not emergently corrected, venous return to the heart is decreased and shock or cardiac arrest may ensue.

FIGURE 27.3. Anteroposterior chest radiograph showing an air–fluid level in the left chest and diaphragm elevation indicative of a traumatic diaphragmatic hernia. The cardiac silhouette is deviated into the right chest.

Pulmonary contusion may not be obvious on the initial chest radiograph but may be seen on CT scan. Hemothoraces and pneumothoraces are managed as in adults. Tracheo-bronchial disruption should be suspected in a child with a tension pneumothorax, massive subcutaneous emphysema, and/or a continuing air leak or persistent collapse of the lung despite a functioning chest tube. The diagnosis is confirmed by bronchoscopy, although multidetector CT (MDCT) scan has the perceived ability to provide detection and detail of pleural, parenchymal, mediastinal, and chest-wall injury, and also seems to have some utility for esophageal, tracheal, and main-stem bronchial disruption and cardiac injury.⁶⁹

Blunt cardiac injuries can occur in children and range from mild to lethal.⁷⁰ The primary mechanisms of injury associated with this diagnosis are motor vehicle and pedestrian-related trauma. It is extremely rare for a hemodynamically normal patient with a normal sinus rhythm to develop a subsequent cardiac dysrhythmia or cardiac failure.⁷⁰ Significant cardiac injuries rarely occur in isolation, and most of these children die at the scene.⁷¹ A few survive and are transported to trauma centers. Use of the FAST examination of the pericardium is a good tool to rapidly identify pericardial fluid in these children and allow for prompt treatment.

Thoracic aortic rupture is a rare injury in children but is highly lethal if undiagnosed. A report from the NPTDR described 28 patients (from a total of 25,301) with traumatic aortic disruptions and a mortality rate of 57%.⁷² Multisystem trauma from motor vehicle crashes or pedestrian collisions are the most common mechanisms. An appropriate mechanism of injury in conjunction with a chest radiograph demonstrating a wide mediastinum should raise suspicion and prompt investigation. Dynamic spiral CT angiography has become a definitive method of diagnosis. Good outcomes can be expected from early diagnosis, temporizing antihypertensive therapy, and definitive operative management including increasing use of endovascular stenting, although there are now reports of successful nonoperative management of both thoracic and abdominal aortic injuries in children.⁷³

Abdominal Trauma

Twenty-five percent of children who sustain trauma have abdominal injuries. Unstable patients should undergo a FAST examination in the trauma room, and those with positive findings in the setting of continued hemodynamic abnormality despite fluid resuscitation should be taken to the operating room. The FAST examination will miss solid organ intraparenchymal injuries without free fluid, and stable pediatric trauma patients with major injury mechanisms or abdominal tenderness are evaluated with an abdominal and pelvic CT scan using IV contrast and then serial physical examinations during inpatient observation.^{74–76} Six findings have been independently associated with intra-abdominal injury, including systolic blood pressure below normal for age, abdominal tenderness, associated femur fracture, serum aspartate aminotransferase concentration greater than 200 IU/L or serum alanine aminotransferase concentration greater than 125 IU/L, urinalysis showing more than 5 RBCs per high power field, and an initial hematocrit of less than 30%.⁷⁷

6 The approach to solid organ injuries (liver, spleen, kidney) discovered on CT scan is primarily nonoperative, as most (more than 90%) of these injuries will heal with conservative management. The kidney is relatively large and anterior, and a significant abdominal blow often manifests with hematuria. However, hematuria is more often associated with a liver or spleen injury than with a radiographically significant renal injury. The indications for operation in children with solid organ injury include evidence of ongoing bleeding, uncorrected base deficit, persistent hemodynamic abnormality, the development of peritoneal signs or other signs and symptoms of an associated gastrointestinal (GI) injury, or major urinary extravasation with a renal injury.⁷⁸ Although most pediatric

patients with blunt abdominal trauma do not require operation, the need for surgical judgment in determining which children fail nonoperative therapy is critical (Fig. 27.4).

There is now general consensus on the indications for intensive care and transfusion and the need for and timing of follow-up imaging procedures, along with the activities allowed after discharge of a child with a liver or spleen injury.^{79,80} A prospective study by the American Pediatric Surgical Association of stable patients with traumatic grades I through IV liver and spleen injuries revealed a very low incidence of nonoperative failures (zero in some centers), a general agreement that transfusions were not required unless the hemoglobin fell below 7 g/dL, and that only children with grade IV injuries needed initial observation in an intensive care unit (ICU).⁸¹ Children may be allowed out of bed when the hematocrit stabilizes, abdominal pain resolves, and hematuria is no longer present (renal injuries). Routine follow-up imaging is unnecessary in the absence of recurrent signs or symptoms of an abdominal complication. Recommendations on activity level after discharge have also been tested prospectively with a very low failure rate (Table 27.3). A reasonable approach to the stable child with a solid organ injury is outlined in Table 27.4. There is evidence that children with splenic injuries treated at trauma centers versus nontrauma centers more often undergo splenectomy, suggesting that dis-

TABLE 27.4 **TREATMENT**

APPROACH TO THE STABLE CHILD WITH A SOLID ORGAN INJURY

- Documentation of the degree of injury by computed tomography scan
- A brief hospital stay based on physiologic status
- Allow ambulation when pain and tenderness resolve
- Allow oral intake when pain and tenderness resolve
- Discharge when eating, ambulating without pain, and stable hematocrit
- Selectively repeat computed tomography scan for those with recurrent signs or symptoms following initial resolution
- Office follow-up before release to return to contact sports and physical education at school

semination of these guidelines may be both educational and reduce the numbers of children having operations following splenic trauma.⁸² A recent study reported that children with high-grade (IV and V) liver injuries have a longer recovery, more complications, and greater use of resources than children with similar injuries to the spleen.⁸³

Pancreatic injuries occur in a low percentage of pediatric trauma patients but carry a high morbidity and mortality risk if overlooked. The mechanism of injury is usually a circumscribed blow to the epigastrium, such as with the handlebars of a bicycle. Pancreatic injuries also may be the result of inflicted trauma, either a fist or shoe. Abdominal tenderness frequently is initially absent. The most sensitive diagnostic study is an abdominal CT scan with oral and IV contrast, but this injury can be missed on the initial scan. The approach to a blunt pancreatic injury is conservative unless major ductal disruption is present.⁸⁴ Postinjury complications include pancreatic fistula or pseudocyst. Both may resolve with drainage alone.

With abdominal and pelvic CT scan as the cornerstone of diagnosis after blunt abdominal trauma in children, and a general nonoperative approach to solid organ injuries, much attention has been directed toward the diagnosis of small-intestinal injuries in these patients.^{85–87} Blunt intestinal injuries occur in 1% to 5% of pediatric patients with abdominal trauma. 7 Hollow viscus injury is difficult to diagnose and requires a high index of suspicion, serial abdominal examination, and select diagnostic studies. Mechanisms of injury involve intrusion-type blows and can include restrained or unrestrained motor vehicle passengers involved in crashes, pedestrians struck by motor vehicles, inflicted trauma, bike handlebar injuries, and direct blows to the abdomen or back (Fig. 27.5). The initial findings on physical examination may be subtle. Findings on CT scan may be equally subtle and include extravasation of oral contrast material, free intra-abdominal air, localized bowel wall thickening or dilatation, and signs of a mesenteric hematoma.⁸⁶ The presence of free pelvic fluid that is not associated with a solid organ injury is especially concerning for an intestinal injury. The presence of a small-intestinal injury also should be suspected when there is abdominal wall ecchymosis associated with spinal (Chance) fractures caused by the inappropriate high-riding use of a lap belt above the iliac crests without a shoulder harness (lap belt complex).⁸⁸ Occasionally, a blunt injury to the abdomen results in a hematoma that causes obstruction but not a transmural bowel wall ischemic injury. This is most common in the duodenum and usually resolves with conservative treatment.⁸⁵ In the presence of clear evidence of a hollow viscus injury, some pediatric surgeons are advocating initial diagnostic and possible therapeutic laparoscopy rather than laparotomy.⁸⁹ At least one study in children who had a missed or delayed diagnosis of GI tract injury showed no significant differences in ICU stay, total length of stay, associated injuries, and mortality compared with children who had a timely diagnosis. However, there was a significant increase in complications including abscess, fistula, wound infection, and delayed intestinal obstruction. Children whose injuries are initially missed exhibit evolving signs of peritonitis including fever, increasing abdominal pain, leukocytosis, and tachycardia (Fig. 27.6).⁸⁷

Associated injuries to the abdominal aorta can also be seen in restrained children who are in high-speed crashes. These injuries are rare and may be diagnosed using CT angiography or aortography, and some can be managed nonoperatively.⁷³

Pelvic Fractures and Extremity Trauma

Fractures are the second most common injury occurring in pediatric trauma patients. The pediatric musculoskeletal system differs greatly from the adult, presenting unique injury patterns and challenges in diagnosis and treatment.⁹⁰ Pediatric

FIGURE 27.5. A: Ecchymosis of the abdominal wall resulting from improperly positioned seatbelt on the torso of a small child. B: Deserosalized segment of jejunum containing enterotomy.

bone contains more collagen leading to reduced tensile strength, reduced propagation of fractures, and improved resilience, but this quality makes radiographic evaluation more challenging. The periosteum is more metabolically active in children, leading to rapid callus formation and union of fractures and a higher potential for remodeling. The growth and change that occur at growth plates facilitate fracture remodeling and rapid healing, but physeal damage can also lead to deformity due to asymmetric limb growth.

Some fractures are unique to children. Greenstick fractures occur when the bone bends before it breaks, and the periosteal sleeve maintains apposition, creating a “hinge effect” without complete fracture of the bone.⁹⁰ Supracondylar fractures are the most common pediatric elbow fracture. Most (95%) are extension fractures due to a fall on an outstretched hand with the elbow hyperextended. Fracture reduction needs to proceed urgently in some cases. The physical examination should focus on the degree of swelling and neurovascular status. Excessive elbow swelling and ecchymosis together with increasing pain or pain with passive finger extension are concerning for ischemia. This injury is also predisposed to development of a

compartment syndrome, although all injured extremities must be monitored carefully with frequent neurovascular examinations for this reason.

Injuries to peripheral nerves are common in all forms of pediatric upper extremity trauma, making early neurologic examination essential. In children who are unconscious, electrodiagnostic studies may be helpful if a neurologic deficit is detected later. Nerve exploration should be considered for open fractures, fractures that require open reduction, or nerve palsies that develop after fracture reduction. For closed fractures associated with nerve palsy at initial evaluation, observation is recommended with exploration reserved for lack of recovery on examination or electrodiagnostic testing after 4 months.⁹¹

Depending on age, location, and type of fracture, options for stabilization and alignment include casting, traction followed by casting, various methods of internal fixation including flexible rods and plates, and external fixation.⁹² External fixation is particularly well suited for open complex fractures, fractures complicated by extensive soft tissue injury, open fractures complicated by a vascular injury, or fractures in multiple trauma victims who will require prolonged rehabilitation.

FIGURE 27.6. A: Jejunal hematoma and perforation at the ligament of Treitz resulting from child maltreatment. This child presented in hypovolemic shock and had a damage-control laparotomy. B: The abdomen was treated open for several days using a conventional, commercially available pediatric silo.

Angiography (diagnostic and/or therapeutic) may be needed in patients with suspected limb ischemia or pelvic bleeding.⁹³ There is some evidence that arterial trauma in ischemic but nonthreatened limbs of very young children (<2.5 years old) can be managed with systemic heparinization.⁹⁴

Blood loss associated with bony injuries, especially in the pelvis, is proportionately greater in the child than in the adult, and this must be considered during volume resuscitation. At significant risk for hemorrhage are patients with bilateral anterior and posterior pelvic fractures.⁹⁵ The presence of multiple pelvic fractures also predicts the presence of associated genitourinary and abdominal injuries.⁹² However, most pelvic injuries in children are not serious and are treated nonsurgically, with protected weight bearing and gradual return to activity.

Delay in diagnosis of fractures is common in both the minimally and the multiply injured child. A representative study of 149 multiply injured Canadian children with 494 total injuries reported a 6% incidence of delayed fracture diagnosis (46% of the 13 missed injuries).⁹⁶ Children who are evaluated in emergency departments after trauma and subsequently discharged home should be asked to ambulate first, to avoid missing an occult fracture.

Fractures can be associated with prolonged immobility, particularly when combined with a TBI. Adults are commonly treated prophylactically to prevent venous thromboembolism. At least one report indicates that pediatric inpatients with the diagnosis of trauma are not at increased risk to develop deep venous thrombosis of the lower extremities.⁹⁷ Nevertheless, adolescent patients who will have prolonged immobility from multiple fractures, pelvic fractures, or spinal trauma may be candidates for prophylactic therapy.

INFLECTED TRAUMA

All physicians caring for injured children have an ethical and legal responsibility to recognize and report the possibility of child maltreatment/abuse or inflicted injuries. The Centers for Disease Control and Prevention estimates that abuse and neglect is responsible for 4.5 of every 10,000 deaths in children 4 years of age and younger. Sadly, most children who die or sustain serious injury from inflicted trauma have a history of previous injury. Deaths or additional injuries are potentially preventable if the abusive behavior is recognized and remediated or the child is removed to foster care.⁹⁸ Inconsistency between the history and the anatomic injury or discrepancies in injury mechanism reported by involved adults should alert the medical provider to suspect maltreatment. Frequently, the child has been taken to several different emergency departments to avoid raising suspicion. Physical signs of inflicted trauma include laceration or tear of the upper frenulum, retinal hemorrhages, multiple subdural hematomas without an acute skull fracture, genital or perianal injuries, burns in unusual areas (including burns caused by cigarettes), multiple torso bruises, and radiographic evidence of multiple old or healed fractures. The spectrum of injuries is variable, but head injuries are the most common injury reported in addition to being the most common cause of death. There is some evidence that children with inflicted TBI have worse outcomes than those with noninflicted injuries as measured with standardized functional and outcome status tools.⁹⁹ Visceral trauma is often associated with skin bruising and may also be associated with a higher incidence of thoracic trauma.¹⁰⁰ If maltreatment is suspected, hospital admission is mandatory and a formal report to the appropriate social agency is required by law in most states.

PERFORMANCE INDICATORS

The pediatric trauma system requires constant reevaluation. Because death after trauma is relatively less common in chil-

dren who are brought to the hospital alive (compared with adults), pediatric performance filters are primarily aimed at reducing morbidity after injury. There are currently few pediatric performance indicators that have been systematically studied. The American College of Surgeons Committee on Trauma *Resources for Optimal Care of the Injured Patient*¹⁹ provides a list of indicators used for verification of pediatric trauma centers (Table 27.5). Participation in systemwide reviews and a commitment to correction of identified problems are required of all professionals caring for injured children to ensure the best possible outcomes.

FUNCTIONAL RECOVERY

Children who survive trauma may experience long-term problems related to both physical and psychological impairment. A subset of children with mild TBI display increased hyperactivity or inattention and conduct disorders, and/or somatic complaints of headaches, photophobia, and dizziness, particularly if injured before the age of 5 years.^{101,102} Cognitive or behavioral changes may be evident as well as problems with school performance or sleep disorders. There are longitudinal studies indicating that depression is a significant problem among adults with pediatric-onset SCI, contributing to poorer outcomes and lower quality of life.¹⁰³ Many children with persistent disability noted at the time of hospital discharge do not receive appropriate rehabilitation services (physical therapy, occupational therapy, and speech services) because of lack of availability, insurance coverage, or parental perception of need.¹⁰⁴ When availability of rehabilitative resources for injured children is lacking, full recovery from injury is limited.¹⁰⁵ One recommendation is to involve the child's pediatrician or primary care physician in the follow-up care, regardless of the postacute services that the child may be receiving.¹⁰⁶

Many published studies describe acute and long-term impairments in behavior, attention, memory, education, and adaptive function following TBI in school-aged children and adolescents.¹⁰⁷ Studies in preschool children indicate long-term impairment in educational performance and daily skills. For children with long-term disabilities resulting from TBI, there is a major impact on both their personal quality of life and that of their family.¹⁰⁸ In addition, many families caring for children after severe TBI are socially disadvantaged, with a large proportion of single, working, minority mothers.^{109,110}

Within the first month after a traumatic event, individuals may display reexperiencing, avoidance, hyperarousal symptoms, and dissociation (feelings of unreality or emotional numbing).¹¹¹ Brief education is appropriate to explain that these symptoms are normal reactions that are likely to resolve. Symptoms that persist for more than a month or are particularly distressing in their intensity may be indicative of post-traumatic stress disorder (PTSD). Symptoms of this disorder in young children include sleep disturbances and nightmares, separation anxiety, difficulties in concentration, intrusive thoughts, difficulties in talking with parents and friends, mood disturbance, deterioration in academic performance, specific fears, and accident-related play. PTSD was reported in 35% of children involved in motor vehicle crashes compared with only 3% of children injured while playing sports.¹¹² Interventional programs that are aimed at both recognition and treatment of PTSD symptoms have the potential to improve functional recovery after injury in children.

A few studies have looked at health-related quality of life (HRQOL) following various injuries. Multiple dimensions of HRQOL are negatively affected among children with moderate or severe TBI and do not improve significantly over the first year after injury.¹¹³ Children requiring hospitalization for extremity fractures suffer dramatic declines in physical and psychosocial well-being during the first 3 months after injury, although children with upper extremity fractures do better

TABLE 27.5

EXAMPLES OF PEDIATRIC PROCESS AND OUTCOMES MEASURES: COMPLICATIONS/PERFORMANCE INDICATORS

■ MEASURE	■ DEFINITION	■ PURPOSE
Missed intubation	More than one attempt to place endotracheal tube appropriately	Efficiency of airway care is the defining variable in outcome for severely injured children. Who, when, what, and how many attempts were required for successful control of the airway are objective measures of system performance.
Unplanned extubation	Unintentional extubation by patient or provider	Failure to maintain the airway can be life threatening. This indicator reflects adequacy of pediatric critical care nursing care.
Extubation within 24 h of rapid-sequence intubation (excluding operative procedures)	Patient can be extubated <24 h after drug-assisted intubation, excluding operative procedure	This measure is the objective monitor of appropriateness of using rapid-sequence intubation, an intrinsically dangerous process. Patients who can be extubated within 24 h may not have required chemical paralysis and intubation in the first place.
Hypocapnia or hypercapnia	Overventilation or underventilation, especially in the first 12 h after injury	These measures are a reflection of efficacy and precision of care in the critical first 12 h after initial stabilization.
Resuscitation volumes	Infusion of more than 50 mL/kg during the first 2 h in child with normal initial vital signs	Judicious fluid management requires careful titration of filling pressures with oxygen-carrying capacity. Inordinate volumes of crystalloid, especially in the absence of clinical findings of hypoperfusion, will potentially exacerbate fluid sequestration in the brain and/or lung. This indicator reflects appropriate attention to clinical detail and accurate recording.
Vascular access problems	Any acquisition of vascular access that takes longer than 5 min to accomplish, especially if intraosseous infusion is not used	This indicator is an objective measure of preparation and facility in accomplishment of a critical, size-related component of pediatric resuscitation.
Unplanned operation following nonoperative management	Any operation for control of hemorrhage in a patient being managed nonoperatively	This indicator is an objective measure of the appropriateness of nonoperative management.
Unplanned hypothermia	Core temperature <35°C for >2 h	Although mild hypothermia has been associated with improved outcomes following brain injury, moderate to severe hypothermia causes a variety of hematologic and metabolic derangements and must be avoided in children.
Nosocomial pneumonia	Pneumonia, defined by NTDS ^a	Pneumonia is a major cause of avoidable morbidity and cost. Recognition of pneumonia is especially important in children without evidence of pulmonary injury or aspiration.
Missed injury	Any injury related to the initial traumatic event diagnosed >24 h after admission	This indicator is an objective measure of the specificity and accuracy of the initial assessment.

^aFrom

than those with lower extremity fractures. Many children with tibia and/or fibula fractures still report poorer physical functioning 1 year postinjury.¹¹⁴

INJURY PREVENTION

Public health experts recommend that injury prevention efforts focus on injuries that are common, severe, and readily preventable. Examples include mechanisms likely to result in head or spinal cord injuries, where there is a high mortality or hospitalization rate and a long-term disability rate and effective countermeasures exist. The Emergency Medical Services for Children (EMSC) program emphasizes a step-by-step approach to injury prevention by establishing goals and objectives with measurable outcomes (Table 27.6).¹¹⁵

Physicians have been cited as the parent's first choice for information on injury control and child safety, but most physicians know little about injury prevention.¹¹⁶ Major educational programs must be aimed at all caregivers to have a significant impact on pediatric trauma mortality rates.

Methods aimed at reducing childhood injury can be described as active or passive. The most successful prevention strategies are those that work automatically (i.e., are passive). Making roadways and vehicles safer has done more to decrease injuries from motor vehicle crashes than asking drivers to adhere to the speed limit or refrain from drinking alcohol before driving. Active intervention requires a behavioral change to be effective, such as securing a child in a safety seat. Recent studies emphasize specific patterns of injury in pediatric car crash victims, advocate continued public education for positioning children in the back seat of cars, and advocate

TABLE 27.6 PREVENTION**NATIONAL EMSC PROGRAM APPROACH TO INJURY PREVENTION**

1. **Conduct a community assessment.** Bring individuals and groups who represent the community at large together to assess regional accomplishments and determine available resources.
2. **Define the injury problem.** Based on the community assessment and any available data, define a problem in specific, quantifiable terms.
3. **Set goals and objectives.** Make your goal a broad, general statement about the long-term changes the prevention initiatives are designed to make and the objective(s) specific, time limited, and quantifiable, in terms of either a *process* or an *outcome*.
4. **Plan and test interventions.** Interventions are the actions that you take to accomplish your goals and objectives. Use the E's of prevention to design options:
 - Engineering* of products and environments
 - Enactment* of legislation to promote safety
 - Education* of children, caregivers, healthcare professionals, and legislators
 - Evaluation* of the efficacy of specific interventions
5. **Implement and evaluate interventions.** Quantitate your results to determine whether your goals and objectives have been met.

for use of appropriate restraint systems (and appropriate use of restraint systems) for young children.^{117–120}

Successful injury prevention programs have resulted in a significant reduction in the number of burn injuries in children, specifically with the development of fire-retardant sleepwear and working smoke detectors. There has been less success in reducing injuries to pediatric pedestrians: risk factors for pedestrian injuries in children include an age of 5 to 9 years, male sex, poverty, household crowding, inadequate parental supervision, family stress, and minority race or ethnic group.¹ Environmental contributions include living on streets with high traffic, lack of pedestrian-control devices, absence of alternatives to the street for play, and a high density of curbside parking. Successful environmental modifications, termed *traffic calming*, have been pioneered in Europe and include diversion of high-speed traffic away from the core of the city and residential areas and decreasing the speed limit to 10 to 20 mph. These changes reduce the risk of injury for all pedestrians, but especially for children. Bicycle helmets are effective in reducing the risk of head injuries by 85% and the risk of brain injuries by 88%, and legislation mandating their use coupled with public awareness translates into a decrease in injury rate.¹²¹ There is evidence that educating pediatricians improves the use of car seats for children. Although the rate of use of car seats for newborns and infants is approximately 75%, their use in toddlers is estimated at only 29%, and more than half of car seats for children are not used correctly. In the child over 4 years or 40 pounds, there is ample evidence that booster seats should be used rather than adult-type restraints. More states now have legislation aimed at this high-risk population.

In the United States, all-terrain vehicle (ATV) crashes account for a rising number of neurologic injuries and deaths in all ages, including children. The injury and death rate substantially increased beginning in 1998 when the 1988 Consent

Decrees between the Consumer Product Safety Commission and the ATV industry expired. This agreement included regulations that restricted operators younger than 16 years, halted the sale of three-wheeled vehicles, and included a mandatory educational safety training module and safety warnings.¹²² Although helmets may reduce the risk of head injuries, many states do not have helmet laws, and juvenile passengers not only frequently drive ATVs but also do not wear helmets.¹²³ At least one study of pediatric ATV injuries found no advantage to wearing a helmet.¹²⁴

A substantial proportion of motor vehicle crashes are alcohol related, and alcohol-related crashes are a serious problem even for the youngest drivers. Drivers under 21 years are more likely than older drivers to be involved in fatal crashes, and their added risk for fatal crash involvement increases more sharply at all levels of alcohol use.¹²⁵ This group has been the target of several interventions to reduce alcohol-impaired driving. These interventions include “zero tolerance” blood alcohol concentration (BAC) standards for drivers under the legal drinking age; graduated driver licensing programs that require new drivers to progress through stages and allow them increased driving privileges as they gain experience; and the 1984 Uniform Drinking Age Act, which required states to adopt a minimum legal drinking age of 21 years. Collectively, these and other targeted interventions have contributed to a decrease in alcohol-related fatal crashes across all age groups during 1982 to 2001, with the largest decrease among drivers under 21 years.^{125,126}

Preventing penetrating trauma is more complicated but still can be done effectively. Laws that make gun owners responsible for storing firearms in a manner that makes them inaccessible to children have resulted in a 23% reduction in unintentional shooting deaths among children where they are in effect.¹²⁷ An injury prevention program in Harlem that included improving environmental safety, supporting community development, providing safe and supervised activities for children and adolescents, and providing effective health education resulted in a 50% reduction in assault and gun injuries in the intervention community, compared with increased injuries in a neighboring community.¹²⁸ Thus, there is hope for curbing the epidemic of pediatric injuries, but it will require a combination of legislative efforts, education of all child care providers, enforcement of existing safety laws, and use of widespread, community-based prevention programs using methods that have proved effective. Comprehensive injury data will allow us to direct our efforts into programs that target serious, common injuries with practical interventions.

CHAPTER 28 ■ GERIATRIC TRAUMA AND END-OF-LIFE DECISIONS

WILLIAM P. SCHECTER

KEY POINTS

- 1 Age older than 65 years significantly increases the risk of death after injury.
- 2 The Injury Severity Score is the most significant variable increasing the risk of death in the elderly.
- 3 Elderly patients taking warfarin have a significantly increased risk of death after head injury.
- 4 The most common cause of injury in the elderly is a fall.
- 5 Elderly trauma victims are often undertriaged despite the increased risk of death and disability associated with advanced age.
- 6 Long-term survival after cardiopulmonary resuscitation in the elderly is unusual.
- 7 Withholding or withdrawing life support is the most common event preceding death in the intensive care unit.
- 8 Decisions to limit critical care must be made in the best interests of the individual patient.

The elderly represent the most rapidly growing sector of our population.¹ Twenty percent of the population of the United States will be 65 years of age or older by the year 2030. Forty percent of all trauma patients will be 65 years or older by the year 2050 if current estimates are correct.² Unintentional injury is the ninth leading cause of death for the population aged 65 and older.¹ Both the dramatic demographic shift in favor of the elderly and the importance of injury as a cause of morbidity and mortality mandate a careful consideration of geriatric trauma, intensive care, and end-of-life decisions.

DEFINITION OF GERIATRIC TRAUMA

Geriatric trauma is usually defined as injury to individuals aged 65 years and older. However, the mortality rate from moderate injury (Injury Severity Score [ISS] 9 to 24) is already increased at age 45.³

PREDICTORS OF MORBIDITY AND MORTALITY

Age, the presence of comorbidities, mortality after injury, and injury severity all affect the risk of morbidity. Older patients are more likely on chronic drug treatment prior to injury and to have chronic medical conditions limiting physiologic reserve. Although elderly patients tend to sustain more severe injuries,⁴ they have almost twice the mortality rate compared with younger patients when stratified for ISS and preexisting medical conditions.⁵ Trauma patients older than age 65 are 4.6 times more likely to die than younger patients ($p < 0.001$) after controlling for ISS and preexisting medical conditions.⁶ The risk of death after injury in the presence of both cardiovascular disease and diabetes is greater in patients over age 65 compared with younger patients with the same diseases.⁶ Functional recovery is also impaired. Elderly survivors of trauma are more likely to lose the ability to walk and transfer independently. The risk is even greater for patients older than age 80.⁷

Comorbidities

Comorbidities are more common in the elderly population and are associated with an increased risk of death following injury. Eighty percent of patients over age 65 have at least one comorbidity and 5% have at least two.¹ The increased relative risk of death with cirrhosis is 4.5, coagulopathy 3.2, chronic heart disease 1.8, chronic obstructive pulmonary disease 1.8, and diabetes 1.2.⁸ In addition, renal disease and malignancy increase the risk of death following injury.^{9,10}

Injury Severity

The average ISS of patients over age 75 is 18, compared with an average ISS of 11 to 12 in younger patients.⁴ Forty-eight percent of patients with an ISS greater than 25 died in a study of 852 trauma patients older than 65. The ISS was the most significant variable correlated with the risk of death. Other variables associated with a mortality rate greater than 80% were hypoventilation, hypotension, and a Glasgow Coma Scale Score (GCS) of 3.¹¹

REASONS FOR INCREASED MORBIDITY AND MORTALITY IN GERIATRIC PATIENTS

Decreased Physiologic Reserve

The cardiac index decreases 1% per year and systemic vascular resistance increases 1% per year. Both the response to adrenergic stimulation and the maximal heart rate are reduced with age.¹² As a result, trauma patients over age 65 have a significantly lower cardiac index, oxygen delivery, and oxygen consumption than younger patients.¹³ Hypoperfusion causing prolonged acidosis leads to a higher mortality rate in trauma patients over age 55 compared with younger patients.¹⁴

Effect of Beta-Blockers

Twenty percent of elderly patients with coronary artery disease and 10% with hypertension take beta-blockers,¹⁵ which inhibit their ability to respond to hypovolemia with tachycardia. Geriatric trauma patients often may not fulfill hemodynamic criteria for trauma team activation despite significant injury.¹⁶ Preinjury beta blockade is associated with an increased risk of death.¹⁷

Effect of Anticoagulation

Warfarin is an important drug in the management of a number of chronic medical conditions common in geriatric patients including atrial fibrillation, deep vein thrombosis, and the presence of a prosthetic heart valve. The risk of spontaneous intracranial hemorrhage for patients taking oral anticoagulation is 1%.¹⁸

3 All elderly patients on warfarin require careful evaluation after injury. A retrospective study of 144 geriatric patients on warfarin with a history of mild head trauma demonstrated clinically significant intracranial injury in 7% of the patients.¹⁹

The mortality rate for 25 elderly head injury patients on warfarin with an average international normalized ratio (INR) of 3.2 ± 0.1 was 48%.²⁰ Patients on warfarin with a supratherapeutic INR (6.5) and severe brain injury (GCS <8) had an even worse outcome, with a mortality rate of 87.8%. Even patients with “minor” brain injury (GCS 13 to 15) who present with an elevated INR (4.4) have a mortality rate of 80.6% caused by continued intracranial hemorrhage after presentation to the hospital.²¹

Rapid correction of an elevated INR is essential after trauma. Correction of an elevated INR with fresh frozen plasma (FFP) and vitamin K within 2 hours reduced the mortality rate from 48% to 10% in patients on warfarin with intracranial hemorrhage and a GCS less than or equal to 14.^{22,23} However, if rapid correction of the INR is required in an emergency, prothrombin complex concentrates (PCCs) are recommended.²⁴ Factor VIIa is also effective in reversing the anticoagulation effects of warfarin in patients with intracranial hemorrhage.²⁵

Elderly patients taking aspirin or clopidogrel appear to be at increased risk for death after head injury. Although one study showed no difference in the frequency of intracranial hemorrhage in patients with or without low-dose aspirin,²⁶ two other studies showed a significantly increased mortality rate for patients taking antiplatelet drugs compared to controls.^{20,27} The effect of platelet transfusions on the mortality rate is unclear.^{27,28}

MECHANISM OF INJURY

4 The most common mechanism of injury in the elderly is falls,²⁹ followed by motor vehicle collisions and pedestrian/vehicle accidents. These injuries result in significant morbidity, mortality, and cost.^{30,31} The mortality rate for elderly patients after pedestrian/vehicle accidents is higher than in any other age group.³¹

INJURY PREVENTION IN THE GERIATRIC POPULATION

The known physiologic, anatomic, metabolic, and neurologic changes associated with aging offer opportunities for intervention to reduce the risk of injury. Primary care providers and family members have an important role in identifying and

modifying risk factors associated with injury. Patients taking multiple medications, particularly sedatives and hypnotics, are at increased risk for falls.³² A careful review and appropriate reduction of unnecessary polypharmacy can reduce the risk of hemodynamic and neurologic side effects that predispose to injury. Periodic screening of geriatric patients for postural hypotension,³³ gait and station abnormalities,^{34,35} visual acuity,³⁶ and cognitive deficits³⁷ can identify patients prone to fall.

Interventions such as medication change, external compression stockings, and education of caregivers can reduce the risk of postural hypotension.³⁸ An organized program of strengthening and coordination exercises can improve strength and balance.³⁹ Modification of environmental factors such as improved lighting; removing obtrusive furniture, slippery floors, and floor coverings; and provision of grab rails and raised toilet seats in washrooms and other high-risk areas are potential interventions that can reduce the risk of falling.⁴⁰ Other important injury prevention measures include automobile seat belts, bicycle helmets, smoke detectors, and hot water heaters limited to less than 48.8°C (120°F).³²

AGE AS A CRITERION FOR TRAUMA CENTER TRIAGE

5 Age is an important criterion for trauma center triage for all of the reasons cited previously. Yet, available evidence indicates that elderly trauma victims are undertriaged.⁴¹ Significantly fewer elderly compared with younger patients with appropriate triage criteria were transported to trauma centers in a study of trauma victims in Maryland.⁴²

The reasons for undertriage of geriatric trauma patients are not known. One possible cause is late presentation of physical findings associated with hypovolemia.¹⁶ Undertriage of geriatric trauma patients is a serious problem because treatment of these patients in a trauma center results in a significantly lower mortality rate.⁴³

Head Injury

The initial presentation of intracranial hemorrhage in geriatric patients may be subtle if preexisting cerebral atrophy or impaired intellectual function is present.²⁹ Subdural hematoma is relatively common because of the fragile bridging veins and increased distance between the dura and brain. Epidural hematoma is less common because of increased dural adherence to the cranium with advancing age.²⁹

The mortality rate and functional recovery after head injury are much worse in geriatric as compared to younger patients.⁴⁴ The effect of age as an independent predictor of death begins at age 45.⁴⁴ The odds of death, persistent vegetative state, or other severe disability increase by 50% with each decade increase in age.⁴⁵ Geriatric trauma patients who present with a GCS less than 8 and an intracranial space-occupying lesion have such a high mortality rate and such a low functional recovery rate^{46,47} that some investigators have suggested withdrawal of aggressive support after 72 hours in the absence of significant improvement.¹² The adverse effect of chronic anticoagulation therapy on outcome after head injury was discussed earlier.

Splenic Injury

Although nonoperative management of hemodynamically stable patients with splenic injury is now standard care,⁴⁸ this approach must be used with caution in geriatric patients because of decreased physiologic reserve in the event of sudden hemorrhage. The success rate of nonoperative management of

splenic injury (approximately 80%) appears to be the same in patients younger and older than age 55.^{49–53} However, the mortality rate was significantly higher in patients older than age 55 for both successful (8% vs. 4%, $p < 0.05$) and unsuccessful (29% vs. 12%, $p = 0.54$) nonoperative management. Nonoperative management of splenic injury was overall less successful for elderly patients with higher-grade splenic injuries compared with younger patients.⁵⁴

Skeletal Injury

Rib Fractures. Rib fractures are serious injuries in elderly patients and are associated with significant morbidity and mortality rates. The risk of pneumonia after isolated thoracic trauma in geriatric patients is three times the risk in younger patients.^{55,56} The mortality rate associated with one to two rib fractures is 12% but is approximately 40% if more than six rib fractures are present.⁵⁷

Chest-wall analgesia and pulmonary toilet are important in the management of rib fractures.⁵⁸ Parenteral opiates should be used with caution because of the risk of respiratory depression. Intercostal nerve blockade with local anesthetics effectively controls chest-wall pain, but unfortunately the duration of anesthesia is limited.⁵⁹ Epidural analgesia is probably the most effective method of pain control after rib fracture⁶⁰ and may be associated with a reduction in mortality rate.⁵⁶ Elderly patients with rib fractures should be admitted to the hospital, be monitored carefully, and receive chest-wall analgesia.

Hip Fractures. Hip fractures are common in elderly osteoporotic women. Patients with periarticular fractures often require primary prosthetic replacement to avoid the risks of delayed union or nonunion, loss of fixation, and osteonecrosis.⁶¹ Timely surgical intervention is critical. The risk of death doubles if surgical treatment of hip fracture is delayed for more than 2 days.⁶² However, elderly hip fracture patients should receive careful evaluation and optimization of acute and chronic medical conditions during the first 24 hours after injury prior to surgery.⁶³

Other Extremity Fractures. Geriatric patients are at increased risk for poor functional outcome regardless of the type of extremity fracture.⁶¹ The timing of orthopaedic surgery depends on the nature and severity of associated injuries and the physiologic status of the patient. As a general principle, surgical correction of unstable extremity fractures should occur as soon as possible after resuscitation, treatment of life-threatening injuries, and optimization of comorbid conditions.

Pelvic Fracture. Pelvic fracture is the most serious skeletal injury in the elderly, with a mortality rate approaching 81% for open pelvic fractures. Pelvic fracture patients older than 55 are three times more likely to require blood transfusions and more likely to require angioembolization than younger patients.⁶⁴ The overall mortality rate for geriatric patients (12.3% to 21%) is significantly higher than for younger patients (2.3% to 6%).^{64,65}

INTENSIVE CARE IN GERIATRIC TRAUMA

A recent study of intensive care unit (ICU) resource utilization indicated that elderly trauma patients had a lower ICU admission rate (36.7%) compared to younger patients (45.5%). The lower ICU admission may be due to the death of more geriatric trauma patients prior to ICU admission. Once admitted, geriatric trauma patients have a longer period of ICU stay compared to younger patients.⁵ The risk of death increases

with the number of complications,⁶⁶ many of which are preventable.⁶⁷

Thirty-nine percent of geriatric trauma patients develop nosocomial infections compared with 17% of younger patients ($p < 0.005$). Nosocomial infections are associated with a mortality rate of 28% for patients older than age 65. Patients with preexisting chronic obstructive pulmonary disease are at particular risk for nosocomial pneumonia.⁶⁸ Aggressive measures to prevent, diagnose, and treat nosocomial infections are essential to improve the outcome of geriatric intensive care patients.¹²

The most appropriate method of hemodynamic monitoring is unknown. Although pulmonary artery catheter (PAC) monitoring has been recommended for critically ill geriatric trauma patients,¹² the PAC is associated with an increased risk of death⁶⁹ and pulmonary embolism,⁷⁰ as well as complications related to insertion and nosocomial infection.⁷¹

Transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) permit minimally invasive assessment of cardiac anatomy, ventricular filling, wall motion, and ejection fraction. Unfortunately, TTE and TEE require extensive training for both the technical performance and interpretation of the examination and require multiple examinations at different points in time.^{72–74} Anticipated improvements in technology offer the hope of efficacious noninvasive hemodynamic monitoring.

OUTCOME FROM CARDIOPULMONARY RESUSCITATION IN THE ELDERLY

- 6 Long-term survival following cardiopulmonary resuscitation (CPR) in the elderly is unusual.^{75–77} Asystole⁷⁸ and failure to restore cardiac activity after 5 minutes of CPR⁷⁹ are variables associated with particularly poor outcome. Advance directives from patients help guide therapeutic discussions for geriatric patients after serious illness or injury.

ADVANCE DIRECTIVES AND HEALTH CARE PROXIES

Advance directives may be executed via a living will or health care proxy.⁸⁰ A living will is a legal document in which a competent person expresses preferences for care in the event of serious illness or injury precluding participation in therapeutic decisions.⁸¹ Unfortunately, a living will can neither predict all potential health care scenarios nor predict a change in patient preferences due to changing circumstances. Trauma surgeons, who have usually not met the patient prior to injury, must at times be guided by a document written years previously without the benefit of a discussion with the patient.

A health care proxy is an individual appointed by a competent person to make proxy decisions in the event of incompetence due to serious illness or injury. Patients and the general public desire advance directives.^{82,83} Lack of physician initiative in discussing advance directives with patients is the major impediment to advance directives.⁸²

WITHHOLDING AND WITHDRAWING SUPPORT IN GERIATRIC TRAUMA PATIENTS

- 7 Withholding or withdrawing life support is now the most common event preceding death in the ICU.⁸⁴ Reasons cited by health care providers for limiting ICU care include brain

death, futility, patient suffering, and anticipated poor quality of life.⁸⁵

The concept of brain death was introduced by Beecher in 1968 to respond to the challenges of the emerging fields of organ transplantation and intensive care.⁸⁶ Current diagnostic criteria include the presence of all of the following signs: (a) irreversible coma, (b) absent brainstem reflexes, and (c) apnea. These findings must be confirmed by serial examinations separated by 6 hours in adults over age 18. Confirmatory tests demonstrating absence of cerebral blood flow must be done if the diagnosis is in doubt.⁸⁷

Futility is a word denoting continued intensive care without hope of survival. Unfortunately, uncertainty and disagreement regarding the futility of continued intensive care in an individual patient are common. Opinions regarding futility are influenced by the skill, experience, and professional background of the clinician as well as personal and cultural values.⁸⁸ While perceived patient suffering is a challenge for the ICU staff, withdrawal of support based solely on patient suffering is not indicated.

Data on the quality of life of geriatric trauma survivors are sparse. The use of anticipated poor quality of life as a criterion to withdraw support is dangerous. Clinicians may substitute their own concept of acceptable quality of life for the patient's. All trauma patients may struggle with the psychological, cosmetic, and functional sequelae of injury.^{89,90} However, withholding or withdrawing support based solely on anticipated poor quality of life is not indicated.

Competition for the limited number of ICU beds is a daily occurrence. The appropriate allocation of this limited resource is a challenge for trauma surgeons.⁹¹ Although social justice is a basic principle of medical ethics,⁹² in the absence of a mass casualty event⁹³ the best interests of the individual patient must guide the clinician's decisions. The medical profession must provide transparent outcome data to inform open public debate regarding appropriate resource allocation. The body politic must set the rules. The medical profession must provide the best possible care given the rules.

Withholding and withdrawing intensive care for hopelessly ill geriatric trauma patients is a necessary part of clinical practice. Unfortunately, advance directives or health care proxies are often absent. The challenge is to identify the patients who are hopelessly ill. Decisions to limit critical care should be made in the best interests of the patient based on the following principles⁹⁴:

1. Diagnostic precision: All patients deserve a precise diagnosis and a search for treatable disease. All patients will be "hopelessly ill" if clinicians fail to diagnose a missed injury, drain pus under pressure, or resect dead tissue.
2. Recognition of an uncertain prognosis: Clinicians must recognize the uncertainty of their prognosis. All patients should be given every chance to improve before withdrawal of support if the prognosis is uncertain.
3. A risk-benefit analysis: The primary responsibility is to the individual patient and the family. The patient's interests are paramount. All decisions must be made in the patient's best interest.
4. Patient autonomy: The autonomy of all patients must be respected, both the competent and incompetent. Clinicians must not substitute their own concepts of quality of life for the patient's.
5. Due deliberation prior to decision: Clinicians should not rush to judgment. A careful consideration of all the issues is essential prior to making these critical decisions.
6. Communication with the patient, family, and professional colleagues: Close communication with the patient, family, and friends is important. Communication utilizes a critical resource for busy clinicians—time. However, failure to spend a small amount of time each day with the patient and professional colleagues will result in the expenditure of

huge amounts of time later on coping with the inevitable conflict and psychological distress caused by lack of communication.

7. Cultural sensitivity: Framing the discussion in the cultural context of the patient and family is extremely helpful. If the clinician is unfamiliar with the culture, assistance from colleagues with the appropriate cultural and linguistic skills can be very helpful in improving the quality of communication.
8. Consensus prior to the final decision: Consensus is absolutely essential prior to withdrawal of support. Dogmatism and unilateral action lead to hostility and legal action. Agreement among all parties can almost always be achieved with daily meetings. Allowing another few days to pass to achieve respectful consensus is a wise course. If consensus cannot be achieved, involvement of the hospital ethics committee may help resolve the conflict. If concerted efforts are made to achieve meaningful communication, failure to reach consensus should be a rare event.

SUMMARY

An increasing number of geriatric patients will require care as a result of injury. Physiologic changes due to aging and multiple comorbidities both increase the geriatric patient's susceptibility and adversely affect the physiologic response to injury. Public and professional injury prevention education efforts have the potential to reduce the risk of injury in the elderly. Aggressive evaluation and treatment of the geriatric trauma patient are essential to minimize potentially preventable death and complications. In spite of all efforts, many desperately ill geriatric trauma patients require prolonged intensive care, presenting medical, rehabilitation, and ethical challenges to the trauma team.

CHAPTER 29 ■ TRAUMA IN PREGNANCY

AMY D. WYRZYKOWSKI AND GRACE S. ROZYCKI

KEY POINTS

- 1 Care of the injured pregnant patient brings the challenge of treating two patients, both with unique physiologic responses to the trauma.
- 2 Anatomic and physiologic changes of pregnancy can alter the maternal response to injury. Knowledge of these changes should be kept in mind as the evaluation and resuscitation of the pregnant trauma patient proceeds.
- 3 Priorities for the resuscitation of the injured pregnant patient are the same as for any other trauma patient. Patient care, however, is altered to accommodate the unique anatomic and physiologic characteristics of the gravid woman.
- 4 Following injury, the fetus is highly susceptible to hypoxia and decreased perfusion. Hypoxia, hypovolemia, and acidosis must be promptly treated and aggressively normalized.
- 5 If fundal height is at the umbilicus, the fetus should be presumed viable.
- 6 A Kleihauer-Betke test should be performed in all Rh-negative pregnant women to determine if fetomaternal transfusion has occurred.
- 7 Fetal evaluation includes fundal height measurement and recording heart tones, heart rate, and movement. Focused abdominal sonogram for trauma is an excellent noninvasive, radiation-free method of evaluating the mother, uterus, and fetus.
- 8 Trauma may require urgent transfusion, which should be type O, Rh-negative blood.
- 9 Liberal but judicious use of radiographic studies is advised for the evaluation of the pregnant trauma patient. An imaging study deemed necessary should not be withheld for fear of potential hazard to the fetus.
- 10 Although the myometrium is relatively elastic, the placenta is not, predisposing it to shear forces at the uteroplacental interface, which may lead to abruptio placentae. Abruptio placentae is the most common cause of fetal demise following trauma and may present as an occult process.

- 1 Although injured pregnant patients make up only approximately 1% of all trauma admissions,^{1–6} the magnitude of the problem is much greater because two patients are being cared for simultaneously. Studies have found that trauma is responsible for up to 46.3% of deaths in pregnant women.^{7,8} In fact, the problem may be underestimated because gravid status may not be routinely recorded on death certificates.⁹

In several series, the rate of fetal death parallels the extent of maternal injury.^{3,8,10} In others, fetal death rates have been reported to be three to four times greater than the maternal death rate, implying that the survival of the mother is not always sufficient to ensure fetal well-being.^{1,2,5,11} Although most trauma involving pregnant patients occurs during the second or third trimester, some reports of domestic abuse show that this occurs most frequently before 18 weeks' gestation and then diminishes between 20 and 30 weeks' gestation.^{1,9,11–13} Motor vehicle crashes occur with equal frequency throughout the gestational period and are the leading cause of fetal death secondary to maternal trauma.^{13–15} An understanding of the anatomic and physiologic changes unique to pregnancy as well as of the principles of resuscitation and treatment after trauma are important to provide the best care for both the injured mother and her unborn child.

ANATOMY AND PHYSIOLOGY UNIQUE TO THE GRAVID PATIENT

- 2 Anatomic and physiologic changes of pregnancy can alter the maternal response to injury (Table 29.1). Knowledge of these changes should be kept in mind as the evaluation and resuscitation of the pregnant trauma patient proceed.

Anatomic Changes

By the 12th week of gestation, the gravid uterus is considered an intra-abdominal organ. Important marks for estimating gestational age include the umbilicus (20 weeks' gestation) and the costal margins (34 to 36 weeks' gestation). During the final 2 weeks of normal gestation, the fetal head descends into the pelvis, placing the fetus at risk for skull fractures or traumatic brain injuries with maternal pelvic fractures. With increasing gestational age, the uterus becomes relatively thin (1.5 cm at term) and the amount of amniotic fluid decreases.¹⁶ As a result, with advancing gestational age, the fetus is more

TABLE 29.1

MANAGEMENT

PHYSIOLOGIC ALTERATIONS IN PREGNANCY

■ SYSTEM	■ CHANGE	■ IMPLICATION
Neurologic	Eclampsia may mimic traumatic brain injury (headache, seizures, hypertension)	Exclude traumatic brain injury (head computed tomography scan) May mask shock
Cardiovascular	Cardiac output increased by 1.0–1.5 L/min Heart rate ↑ 10–15 bpm Blood pressure ↓ 5–15 mm Hg in second trimester but returns to normal in third trimester Plasma volume increase by 50% Vena cava compression	Delayed signs of shock Supine hypotension syndrome
Respiratory	Residual lung volume decreased Chronic respiratory alkalosis	Decreased buffering capacity
Gastrointestinal	Decreased gastrointestinal motility	Increased propensity toward aspiration and vomiting
Genitourinary	Dilatation of renal system	Physiologic hydronephrosis and urinary stasis
Laboratory values	Increased white blood cell count Decreased hematocrit Increased fibrinogen and factors VII, VIII, X, and XII	Difficulty interpreting clinical picture regarding hemorrhage Hypercoagulable stage

vulnerable to injury, especially when the mother receives a direct blow to the abdomen. Although the myometrium is relatively elastic, the placenta is not, predisposing it to shear forces at the uteroplacental interface, which may lead to abruptio placentae (Fig. 29.1).

Cardiovascular

Maternal blood volume (plasma and erythrocytes) begins to increase during the first trimester but expands most rapidly

FIGURE 29.1. Placental abruption. Computed tomography scan demonstrating placental abruption. The arrow points to an area of active extravasation of contrast consistent with ongoing hemorrhage. (Reprinted with permission from Jeffrey M. Nicholas, MD, FACS.)

during the second trimester, reaching approximately 45% (6.5 to 8 L) above nonpregnant levels.^{17–19} The increase in plasma volume is proportionally greater than the enlarged erythrocyte volume and results in the physiologic anemia of pregnancy. Near term, the plasma volume continues to expand, but the red cell mass begins to increase, resulting in a near-normal hematocrit. Pregnancy-induced hypervolemia supplies the extraordinary demands of the enlarged uterus, allows for fewer red blood cells to be lost during parturition, minimizes the loss of oxygen-carrying capacity associated with hemoglobin, and protects the mother from the hypotensive effects of impaired venous return.²⁰ This physiologic hypervolemia masks volume loss after trauma and may give the clinician an unfounded sense of security about the patient's hemodynamic stability. Almost 35% of the mother's blood volume may be lost before maternal signs of shock are noted.²¹ Placental vasculature is dilated at baseline, but exquisitely sensitive to catecholamines. Maternal hypovolemia and the presence of circulating catecholamines may result in increased uterine vascular resistance, diminished placental blood flow, and diminished fetal oxygenation even with normal maternal vital signs.²² In fact, fetal distress may be the first manifestation of maternal hypovolemia.²³

As pregnancy progresses, cardiac output increases up to 50% above normal until the 24th week of gestation, after which it plateaus. This increase in cardiac output is a result of a modest rise in heart rate and stroke volume related to the expanded blood volume and the direct inotropic effect of estrogen.²⁴

If the pregnant patient is in the supine position, the inferior vena cava is partially obstructed by the gravid uterus. This decreases venous blood return to the heart, lowers cardiac output, and results in supine hypotension. Turning the pregnant patient onto her left side improves venous return and increases cardiac output by approximately 30%.²⁵

Overall, cardiac work is increased with pregnancy because of the volume load and estrogen effect, despite a decrease in systemic vascular resistance mediated by prostaglandin, progesterone, intracellular calcium flux, and endothelial-derived factors.²⁶ Early in pregnancy, the blood pressure, especially the diastolic level, decreases but then slowly returns to normal by term. Mean normal values for the first trimester are 105 mm Hg systolic and 60 mm Hg diastolic; for the second trimester, 102

and 55 mm Hg, respectively; and for the third trimester, 108 and 67 mm Hg, respectively. Significant elevation above these levels may indicate pregnancy-induced hypertension.²⁷

Finally, the enlarged uterus causes the heart to be displaced upward and to the left. This change, along with the common development of a serous pericardial effusion,²⁸ results in an enlarged cardiac silhouette and increased pulmonary vascular markings on the chest radiograph.²⁹

Pulmonary

The thoracic cavity undergoes significant reconfiguration during pregnancy. The subcostal angle increases and the chest circumference expands 5 to 7 cm. As the uterus enlarges, the level of the diaphragm rises approximately 4 cm. The rise of the diaphragm decreases the volume of the lungs at rest, reducing both total lung capacity and functional residual capacity. At the same time, there is a 5% to 10% increase in inspiratory capacity. The net result of these changes is that pregnancy is a state of chronic hyperventilation with a 30% to 40% increase in minute ventilation inducing a chronic respiratory alkalosis. The maternal alkalosis facilitates the transfer of fetal CO₂ to the maternal circulation. Acidosis in the pregnant patient significantly compromises fetal-maternal gas exchange and must be avoided.³⁰

Gastrointestinal

As pregnancy progresses, the enlarged uterus stretches the abdominal wall and compresses the viscera. This results in a diminished response to peritoneal irritation and altered or referred pain perception, diminishing the accuracy of the clinical exam. Progesterone diminishes the tone of the lower esophageal sphincter and decreases both gastric tone and motility. As a result, the pregnant patient is at significant risk for aspiration.

Renal

Throughout pregnancy, the renal collecting system enlarges to meet the demands of the increased blood volume and urine formation. The renal pelvis and ureter dilate early in the first trimester, resulting in a mild hydronephrosis and hydroureter.³¹ Urinary stasis in the collecting system predisposes the pregnant woman to pyelonephritis. In the first trimester, the renal blood flow and the glomerular filtration rate increase by up to 50%; consequently, the levels of creatinine and blood urea nitrogen (BUN) decrease.³² The clinical significance is that normal or slightly elevated levels of creatinine or BUN may signify renal dysfunction.

Musculoskeletal

The relaxation of the interosseous ligaments during pregnancy causes increased mobility of the sacroiliac and sacrococcygeal joints and widening of the symphysis pubis. These changes, coupled with an enlarged uterus, result in lordosis, disrupt the maternal center of gravity, and increase the risk for falls.

Laboratory Values

The peripheral blood leukocyte count increases to approximately 12,000 cells/mL during gestation and may be as high as 25,000 cells/mL during labor.³³ The platelet count may

appear falsely low because of dilution from increases in plasma volume. Fibrinogen (factor I) and factors VII, VIII, IX, and X are increased considerably during pregnancy, but prothrombin (factor II) is increased only slightly. Although there is a slight decrease in the protein S level and its activity,³⁴ levels of antithrombin III and protein C show no significant change during pregnancy. The level of plasminogen (profibrinolysin) in plasma increases significantly, most likely induced by estrogen.

INITIAL ASSESSMENT AND MANAGEMENT

- 3 Priorities for the resuscitation of the injured pregnant patient are the same as for any other trauma patient. Patient care, however, is altered to accommodate the unique anatomic and physiologic characteristics of the gravid woman.³⁵

The best therapy for the unborn child is expedient maternal resuscitation. An adequate airway with supplemental oxygenation is essential to prevent fetal hypoxemia. Because fetal blood functions on a different oxyhemoglobin dissociation curve, small positive increments in maternal oxygen concentration improve oxygen content and physiologic reserve for the fetus, even if maternal arterial oxygen content does not change appreciably. Maternal hemorrhagic shock, with its resultant release of catecholamines, causes uterine artery vasoconstriction, reducing uterine perfusion and compromising fetal viability. Hence, vigorous crystalloid resuscitation is encouraged, even for patients who appear normotensive. In late pregnancy, compromised cardiac output and blood pressure secondary to vena cava compression can be relieved by placing the patient in the left lateral decubitus or right hip-flexed position. A nasogastric tube should be inserted because of the pregnant patient's increased propensity toward vomiting and aspiration. Urinary volume per hour should be monitored to provide some indication of perfusion status. A focused abdominal ultrasound examination should be performed to look for intraperitoneal hemorrhage in the mother. Goodwin et al. found that ultrasound in the pregnant trauma patient detects intraperitoneal fluid with a sensitivity, specificity, and accuracy similar to that of nonpregnant patients.³⁶

History and Physical Examination

The secondary survey consists of a thorough history (including obstetric history), physical examination, and fetal monitoring if indicated by gestational age.³⁷ Maternal prenatal history is crucial and may alter management decisions if medical problems such as preeclampsia, diabetes, essential hypertension, or congenital heart disease are present. Obstetric history includes the date of the last menstrual period, the expected date of confinement, the perception of fetal movement, and the status of the current and previous pregnancies. If the mother is unable to provide the gestational age, it can be estimated from the fundal height. Fundal height at the umbilicus represents approximately 20 weeks' gestation and the fetus should be considered viable unless an obstetrician determines otherwise. Pelvic and rectal examinations are performed with special attention to vaginal discharge (amniotic fluid or blood), effacement, dilation, and fetal station.³⁸ Vaginal bleeding is always abnormal and may be a sign of labor, placental abruption, placenta previa, or uterine rupture.^{39,40}

- 6 Fetomaternal hemorrhage occurs in 20% of injured pregnant patients. The Kleihauer-Betke (KB) test detects fetal cells in the maternal circulation, indicating fetomaternal hemorrhage, and should be obtained in all Rh-negative pregnant women. If an Rh-negative woman has a positive KB test, she

should receive Rh immunoglobulin. The initial dose is 300 μg followed by an additional 300 μg for each 30 mL of estimated fetomaternal transfusion.^{41,42}

Fetal Assessment and Monitoring

- 7 Fetal evaluation consists of uterine assessment, fundal height measurement, and recording of heart tones, heart rate, and movement. Uterine tenderness and contraction may be related to abruptio placentae, which can occur in the absence of vaginal bleeding. Continuous fetal monitoring is the best predictor of a healthy or distressed fetus. Normal fetal heart rate is 120 to 160 beats per minute; both fetal tachycardia and bradycardia may indicate fetal distress. There is still no consensus on the indications for fetal monitoring in trauma patients. A guideline for patients with major injuries, including shock, is to provide continuous fetal monitoring for at least 24 hours.⁴³

DIAGNOSTIC MODALITIES

- After patient stabilization, several diagnostic modalities are used to define the extent and type of injury for the mother and fetus. Initially, laboratory studies are obtained. If blood is urgently needed, type O, Rh-negative blood is chosen. Evaluation of the abdomen may be performed by ultrasound, computed tomography (CT) scan, or diagnostic peritoneal lavage.⁴⁴ Reliance on ultrasound to evaluate both the mother and the fetus obviates the need to perform a CT scan in some cases and can provide valuable information on fetal motion, heart tones, location, and placement. If diagnostic peritoneal lavage is elected, the open, supraumbilical technique is recommended.
- 9 Liberal but judicious use of radiographic studies is advised for the evaluation of the pregnant trauma patient. An imaging study deemed necessary should not be withheld for fear of potential hazard to the fetus. Factors contributing to the sequelae of prenatal exposure to ionizing radiation are the stage of development, the exposure time, the dose delivered, and the dose absorbed. The absorbed radiation dose varies according to many factors, including instrument model, desired image quality, and distance from the radioactive source. The roentgen (R) is the unit of exposure, and the centigray (cGy) or rad is the unit of absorbed dose. Approximate absorbed fetal doses for radiographic tests are presented in Table 29.2. There is no medical justification for terminating pregnancy in women exposed to 5 cGy or less.⁴⁵ A 0.1% increase in the rate of spontaneous abortion during the first 2 weeks of development follows a dose of 10 cGy, and there is a 1% increase in congenital abnormalities at the same dose.⁴⁶ Another concern is the potential for late neoplasia development. The risks for radiation-induced cancer after in utero exposure during the second and third trimesters are estimated to be 1 in 15,000 children if exposed to 1 mGy x-radiation.⁴⁷ If the fetus receives 50 mGy, the risk is increased to 1 in approximately 300 children. Prudent judgment and foresight by the physician should ensure that specific radiographic studies are ordered and accurately performed to avoid repetition.

BLUNT TRAUMA

Motor vehicle crashes remain the chief cause of blunt trauma in the pregnant patient. As pregnancy progresses, the uterus becomes more vulnerable, rising out of the protective bony pelvis, and it absorbs most of the impact of blunt abdominal trauma. These factors often result in direct fetal injury, usually

TABLE 29.2 **DIAGNOSIS**

APPROXIMATE FETAL DOSES FROM COMMON DIAGNOSTIC PROCEDURES

■ EXAMINATION	■ MEAN EXPOSURE (mGy)	■ MAXIMUM DOSE (mGy)

skull fracture or intracerebral hemorrhage. Pelvic fractures in the gravid patient may cause extensive maternal retroperitoneal hemorrhage as a result of engorged pelvic veins.

Uterine rupture is a catastrophic and fortunately rare complication of blunt abdominal trauma. The incidence is approximately 0.6%.³⁹ Fetal mortality approaches 100% and associated maternal mortality is 10%.²²

- 10 *Abruptio placentae* is the most common cause of fetal death after maternal injury. This carries a 30% to 70% rate of fetal death and a 1% maternal mortality rate. Over 50% placental separation invariably results in fetal demise.⁴⁸ Abruptio placentae can occur in the absence of obvious abdominal injury, because maternal shock is a far greater stimulus for abruption than are the mechanical forces of trauma disrupting the placenta.³⁸ Abruptio placentae is more common in the presence of hypertension, diabetes mellitus, advanced age, multiparity, and maternal use of tobacco or cocaine. Abruptio placentae presents with vaginal bleeding (in 80% of cases), abdominal pain, disseminated intravascular coagulation due to thromboplastin release, and inexplicable maternal hypovolemia. It invariably occurs within 48 hours after trauma, and pregnant patients who are at risk should be monitored accordingly.

The pregnant patient with minor injury should be observed for several hours. Most patients with insignificant trauma do not require admission unless specific signs and symptoms, such as vaginal bleeding, abdominal cramps, or leakage of amniotic fluid, are present. In one series, only 1 of 11 patients had symptoms after minor trauma, and pregnancy outcome was successful.⁶ Occult abruptio placentae has been reported after motor vehicle accidents in which the patient displayed only subtle clinical signs and symptoms. Because placental separation can occur with rapid deceleration injuries, a three-point restraint system appropriately applied is recommended for

pregnant automobile passengers.^{49–51} The mechanism of injury may provide invaluable information regarding potential injuries in even a healthy-appearing patient. At a minimum, a prompt and thorough maternal assessment, fetal assessment, and comprehensive search for injuries are necessary for evaluating the pregnant patient with minor trauma.

PENETRATING TRAUMA

The perinatal mortality rate from penetrating injury to the mother has been reported to range from 47% to 71%.⁵² In general, pregnant women with gunshot wounds to the abdomen should undergo celiotomy. For those who sustain stab wounds to the abdomen, management is based on the likelihood of intra-abdominal injury. The abdominal examination may be unreliable because of a diminished response to peritoneal irritation and altered or referred pain perception. If the clinical presentation is unclear (e.g., absence of peritonitis or evisceration), then a diagnostic peritoneal lavage performed with the open technique in the supraumbilical area may be diagnostic.

OPERATIVE MANAGEMENT

General anesthesia is preferred for the gravid patient with multisystem injury. The risks of anesthesia are related to the physiologic changes that accompany pregnancy. For example, because aspiration is more likely, rapid-sequence induction with cricoid pressure is preferred. Both thiopental and etomidate are good induction agents in pregnancy. As a general rule, ketamine should be avoided as it increases uterine tone and may decrease placental perfusion. Both depolarizing and non-depolarizing neuromuscular blocking agents cross the placenta. This must be remembered because if delivery is required, the infant will be hypotonic and apneic. Volatile agents should be used, if tolerated, as they relax the uterine smooth muscle and blunt the maternal catecholamine response, both of which improve uterine perfusion.⁵³

The standard vertical midline incision is used for maternal celiotomy. Adequate visualization of viscera is mandatory, and the pregnant uterus should not interfere with abdominal exploration or repair of an injury. If labor ensues, vaginal delivery is almost always encouraged. Even early in the postoperative period, vaginal delivery is still preferred and does not appear harmful to the mother or the neonate. Cesarean section prolongs the operative time and increases blood loss, generally by approximately 1 L. Indications for cesarean section during celiotomy for trauma are listed in Table 29.3.

If fetal delivery is cesarean, the uterus is incised longitudinally. After the amniotic membranes are ruptured, the fetus is delivered, and the placenta is removed. The uterus is closed in a running-locking fashion using large, absorbable suture. Once the uterus is evacuated, postpartum hemostasis begins. In cases of uterine atony, bimanual compression of the uterus and the intravenous administration of oxytocin are begun. In addition, the surgeon should examine the uterus and cervix for any lacerations and ensure that the uterus is thoroughly evacuated. Other measures to control severe hemorrhage include intravenous methyl ergonovine, or intramyometrial injection of 15-methyl prostaglandin F_{2a}. For the most part, massive hemorrhage associated with emergent cesarean section in the injured women is associated with a pelvic fracture. Packing of the pelvis or embolization of the internal iliac arteries may be needed as well.

Successful outcome of a postmortem cesarean section depends on the duration of the gestation and the time interval between maternal death and delivery. Under optimal conditions, at 26 to 28 weeks' gestation, the estimated fetal survival

TABLE 29.3

TREATMENT

INDICATIONS FOR CESAREAN SECTION DURING CELIOTOMY FOR TRAUMA

- Maternal shock, pregnancy near term
- Threat to life from exsanguination (injury or disseminated intravascular coagulation)
- Mechanical limitation of maternal treatment
- Risk of fetal distress exceeding risk of prematurity
- Unstable thoracolumbar spinal injury

rate is approximately 50%. Therefore, postmortem cesarean section is justified if the estimated gestational age is at least approximately 26 to 28 weeks. If the time between maternal death and delivery is less than 5 minutes, the fetal prognosis is considered excellent. If the time since maternal death is prolonged to approximately 20 minutes, fetal prognosis is poor. Uncertainty about maternal death time is not a contraindication for this procedure.⁵⁴

CRITICAL CARE MANAGEMENT

Critical care management of the traumatized pregnant patient covers a wide range of topics. The basic principles of hemodynamic monitoring, adequate ventilatory support, nutrition, and careful assessment of volume status apply to the injured pregnant patient and are covered in more detail in other chapters. Knowledge of the disease processes that can arise in the pregnant patient within the first 24 hours after injury allows the physician to render high-quality critical care to the traumatized patient and her unborn child.⁵⁵

When administering medication to the gravid patient, potential risk versus therapeutic benefit must be considered especially carefully. Prophylactic tetanus immunization should be given appropriately, with anti-D globulin for patients who are Rh negative and at risk for isoimmunization. Prophylactic antibiotics are administered if needed, but tetracycline and most sulfa drugs should be avoided.

CARDIOPULMONARY RESUSCITATION

The enlarged uterus compresses the vena cava, resulting in a 25% decrease in cardiac output as a result of decreased venous return. To improve the effects of cardiopulmonary resuscitation (CPR), patients before 24 weeks' gestation can be maintained in the supine position but with manual displacement of the uterus laterally. After 24 weeks' gestation, a procedure table with a 30-degree left lateral tilt is helpful, although CPR is only 80% effective when performed with the patient in this position. Emergent cesarean section may be needed if the patient does not respond to CPR within approximately 5 minutes.^{56,57} Morris et al. found that if the fetus is viable (presence of fetal heart tones) and is at least 26 weeks' gestation, emergent cesarean section is justified; they found that infants who met these criteria had a survival rate of 75%.⁵⁸

TOXEMIA OF PREGNANCY OR PREECLAMPSIA (PREGNANCY-INDUCED HYPERTENSION)

Any traumatized pregnant patient presenting with seizures or coma should have head injury excluded. Toxemia of pregnancy should also be included in the differential diagnosis. In the

severe state, eclampsia is manifested by hypertension, pulmonary edema, elevated liver function enzymes, proteinuria (i.e., HELLP syndrome), and seizure activity. The pathophysiologic cause is vasospasm, which affects hepatic, renal, cerebral, and placental blood flow. Despite the presence of pulmonary edema, intravascular volume depletion is often present, and a fluid challenge may be appropriate. Rapid control of the hypertension is achieved with hydralazine.⁵⁹ However, elevated maternal oxygen consumption disrupts uterine vascular oxygen supply and maternal equilibrium, resulting in fetal distress. Smoother control of reduction in blood pressure and myocardial oxygen consumption is accomplished by achieving volume expansion before vasodilation. Inotropic support, in combination with vasodilator treatment, maximizes oxygen delivery and affects afterload reduction. Magnesium sulfate has a slight hypotensive effect but does not decrease systemic vascular resistance.

THROMBOEMBOLISM

Pregnant patients are at increased risk of thromboembolism from all three components of the Virchow triad: stasis, intimal damage, and hypercoagulability. Increased venous capacitance, vena cava compression, and weight gain promote venous stasis. Labor and trauma cause intimal damage, and hypercoagulability results from elevated levels of fibrinogen and intrinsic coagulation factors with the gravid state. Advanced age and multiparity further increase these risks. No method of prophylaxis has been demonstrated to be both safe and universally effective in preventing thromboembolism, either in the patient with multiple injuries or in the pregnant patient. In general, warfarin is avoided because it is associated with congenital anomalies if given to the mother in the first trimester and has been shown to cause serious fetal bleeding when administered during the second and third trimesters.^{60,61} If chemical venous thromboembolism prophylaxis is indicated in the pregnant patient, the American College of Chest Physicians currently recommends the use of low-molecular-weight heparin over unfractionated heparin.⁶²

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism after trauma in pregnancy or parturition is characterized by hypotension, hypoxemia, and coagulopathy. The diagnosis is often difficult, and an 80% mortality rate has been reported. Amniotic fluid debris enters the maternal venous circulation, causing sudden dyspnea and hypotension. A mixed metabolic acidosis and respiratory alkalosis ensue. The chest radiograph shows characteristic pulmonary edema or an acute respiratory distress syndrome (ARDS) pattern. Hemodynamically, the patient has an elevated pulmonary capillary wedge pressure and a low systemic vascular resistance. Disseminated intravascular coagulation develops in approximately 30% of these patients. Although most cases of amniotic fluid embolism occur during labor, it has been reported to occur after abdominal trauma⁶³ and abruptio placentae. This diagnosis is established on clinical findings, and the treatment consists of supportive care (i.e., oxygenation, maximization of hemodynamic parameters, and correction of coagulopathy).

INTERPERSONAL VIOLENCE

Although motor vehicle crashes and falls are the most common causes of trauma during pregnancy, reports indicate that 4% to 17% of pregnant women are victims of interpersonal violence.²⁻⁴ In fact, this number may be underestimated because population-based prevalence estimates are often

unavailable, pregnancy is not consistently recorded on death certificates,⁹ and, as with many abuse crimes, it is not frequently reported.

Poole et al. reported that 64 (31.5%) of 203 injured pregnant patients experienced interpersonal violence.¹¹ Of the eight fetal deaths in this series, three occurred 7 days after injury and five occurred in women with an Injury Severity Score of zero. These findings indicate that severe trauma to the fetus may occur without obvious injury to the mother, emphasizing the need for the physician to question the patient directly about abuse. Furthermore, physicians should be encouraged to take measures for early intervention, such as establishing a link with agencies that deal with battered women, so that physical protection, emotional support, and information about legal rights are readily available.

SUMMARY

The pregnant trauma victim presents a unique challenge to the resuscitating physician. Two patients are being treated, and a high degree of expertise is needed to treat both. Initially, evaluation should involve the cooperative efforts of the emergency physician, trauma surgeon, obstetrician, and obstetric nurse. If the pregnancy is near term or delivery is anticipated, a pediatrician and pediatric surgeon should be consulted. The pregnancy should not distract the surgeon from initiating basic resuscitation. Equally important, the injury should not confound the obstetrician. The expertise of the obstetric nurse is useful in coordinating the overall care plan for the mother and her unborn child. Expedient, accurate resuscitation of the mother takes priority because the best chance for fetal survival is maternal survival.

CHAPTER 30 ■ CRITICAL CARE AND POSTINJURY MANAGEMENT

GRANT E. O'KEEFE

KEY POINTS

- 1 Adequate resuscitation is critical to avoid ongoing occult hypoperfusion and subsequent complications by using a protocol for physiologic endpoints, including central venous pressure.
- 2 Hypothermia occurs due to ongoing heat loss and metabolic failure requiring large amounts of energy production and thus oxygen consumption. There is no proven benefit for hypothermia in traumatic brain injury (TBI) outcomes.
- 3 Coagulopathy is common and due to both dilution and consumption while being aggravated by hypothermia. Early empiric replacement of coagulation components reduces mortality.
- 4 TBI is a major cause of injury-related death, with care directed at avoiding secondary brain injury, control of elevated intracranial pressure, and early recognition of treatable mass lesions.
- 5 Elevated intra-abdominal pressure (abdominal compartment syndrome) causes a tense distended abdomen, hypoxia, oliguria despite adequate volume, and impaired cardiac output, requiring decompression and an open abdomen in severe cases.
- 6 Acute lung injury and acute respiratory distress syndrome require adequate, frequently higher levels of positive end-expiratory pressure; low tidal volumes; and moderate

levels of fraction of inspired oxygen to optimize recovery.

- 7 Venous thromboembolism remains an important and potentially preventable cause of morbidity and mortality. Prophylactic anticoagulation in high-risk patients must often be balanced with increased risk of hemorrhage.

- 8 Nosocomial infections are the most common complication requiring aggressive prevention, diagnosis, and preemptive empiric antibiotic therapy with subsequent de-escalation for ventilator-associated pneumonia, urinary tract infections, catheter-related bloodstream infections, and surgical site infections.

Most deaths occurring in trauma patients who survive to reach a trauma center occur in the intensive care unit (ICU). Furthermore, the most costly complications occur in and require treatment in the ICU.^{1,2} Most of these deaths and complications are the consequence of severe hemorrhage and traumatic brain injury, and others are related to injury-induced alterations in coagulation and inflammatory and innate immune responses. Understanding their biology, epidemiology, and clinical features will help focus our resuscitative and definitive care efforts in these patients.^{3,4}

Trauma patients experience shared physiologic changes and complications with noninjured critically ill patients. They also experience others that, if not unique to, are particularly relevant to trauma patients. The sections that follow are organized temporally in an effort to reflect when specific situations are most likely to be encountered in the postinjury period. The time periods that follow provide a framework in which to think about the challenges these patients face as they arrive in the ICU from the operating room, emergency department, and elsewhere.

STABILIZATION AND SECONDARY SURVEY (INITIAL 24 HOURS POSTINJURY)

This phase is often a continuation of emergency department or operating room stabilization of vital functions and the ongoing diagnosis and management of life-threatening injuries. In other circumstances, resuscitation is complete, but secondary or “tertiary” surveys to search for occult injuries are undertaken, optimal support of vital organ function is continued, and careful monitoring for deterioration is required.

Hemodynamic Resuscitation: Monitoring and Targets

Tissue injury, local and global ischemia, and hypoxia are well-known contributors to subsequent multiple organ dysfunction syndrome (MODS), nosocomial infection, and other complications after severe injury.^{5,6} The duration and degree of shock both increase the risk for subsequent organ dysfunction and severe nosocomial infection after various types of trauma (blunt, penetrating, and burn injury).^{6,7} Therefore, rapid and adequate resuscitation is a critical component of the initial ICU care of trauma patients. However, there are no definitive markers of adequate resuscitation. Arterial base deficit and arterial lactate concentration are good indicators of the severity of injury and are a function of the degree and duration of shock. However, they correlate poorly with other “real-time” measures of tissue perfusion. Excessive attempts to normalize these values may lead to overresuscitation. Serum lactate concentrations and base deficit often remain elevated for hours after perfusion is appropriately restored, in part because they reflect adrenergic stimulation of $\text{Na}^+/\text{K}^+/\text{ATPase}$, which increases lactate production unrelated to tissue hypoxemia.^{8,9} In addition, other biochemical or physiologic markers may only be obtained by invasive means, which are not warranted in most cases.

Therefore, and in recognition of the limitations of these physiologic endpoints, this early phase should initially be

guided by the objectives of normalizing heart rate and blood pressure, achieving adequate urine output (0.5 mL/kg per hour in adults and 1.0 mL/kg per hour in children), and approximating an appropriate central venous pressure (CVP; 10 to 15 mm Hg), measurements that can be obtained simply from an indwelling bladder catheter, an arterial line, and a central venous line. Measuring CVP is important in the critically injured to guide resuscitation and may help distinguish hypovolemia from other less common causes of shock, such as pump failure from myocardial contusion or tamponade.¹⁰ Overly aggressive crystalloid resuscitation or, conversely, inappropriate early use of vasopressor agents prior to adequate resuscitation have each been associated with poor outcomes after trauma.¹¹ Taken together, this information mandates careful attention to resuscitation strategies, collection of appropriate data, and judicious use of crystalloid and vasoactive agents.^{12,13}

Clinical trials have shown that routine pulmonary artery catheter (PAC) use does not improve outcome in critically ill patients.¹⁴ Furthermore, observational studies in trauma patients also do not demonstrate an overall survival advantage.¹¹ However, there are circumstances where additional information is needed to guide resuscitation. Invasive monitoring may be indicated when the patient remains hypotensive despite seemingly adequate intravascular volume, based on an adequate CVP, or when shock is accompanied by severe hypoxemia and additional fluid resuscitation may, in fact, worsen oxygenation. In patients who arrive in the ICU with unstable parameters after receiving large-volume resuscitations in the operating room or emergency department, invasive monitoring may be helpful in clarifying the patient's intravascular volume status and help determine whether additional volume, vasoactive medication, or both are necessary. When a PAC is used, recommended targets are a cardiac index of ~ 3.5 to 4.0 L/min per m^2 and an oxygen delivery index ~ 500 mL/min per m^2 .

In addition, there are a number of potential alternatives to invasive monitoring with a PAC. These include continuous measurement of central venous oxyhemoglobin saturation (ScvO_2) (rather than mixed venous oxyhemoglobin saturation [SmvO_2] with a PAC), which has been shown to improve survival when used early in the management of patients with sepsis.¹⁵ Transthoracic echocardiography and transesophageal Doppler have been studied as possible alternatives to invasive PAC monitoring. Limited transthoracic echocardiography can be used to assess preload and cardiac index. However, there are often physical impediments to its use (particularly subcutaneous air), its correlation with concurrent measurements from a PAC is modest, and it has not been shown to predictably influence patient management or outcome.¹⁶ Transesophageal Doppler monitoring of cardiac function is a more promising technique. When used to guide resuscitation in the initial 12 hours after admission to the ICU, it influences volume resuscitation choices and may improve outcomes in critically ill trauma patients.¹⁷ A summary of resuscitation targets is included in Table 30.1.

Hypothermia

- 2 Hypothermia (core temperature $\leq 34.5^\circ\text{C}$) is less common in trauma patients arriving in the ICU than it was in the past. This is likely due to more aggressive prevention in the emergency department, radiology suite, and operating room. However, it remains a preventable and treatable situation that contributes

TABLE 30.1**HEMODYNAMIC RESUSCITATION PARAMETERS DURING INITIAL 24 HOURS AFTER INJURY**

Urine output: 30 mL/kg/h
Hemoglobin: 12–15 g/dL
Heart rate: ≤100/min
Arterial blood pressure: ≥120 mm Hg
Central venous pressure: 10–15 mm Hg
Cardiac index: 3.5–4.0 L/min/m ²
Oxygen delivery: 500–550 mL O ₂ /min/m ²
Mixed venous oxyhemoglobin saturation: ≥65%
Central venous oxyhemoglobin saturation: ≥70%

to complications and death. Thermoregulation is compromised in severely injured patients by shock and failure of cellular metabolism. Hypothermia from metabolic failure is often exacerbated by external heat loss through the four general mechanisms of energy transfer: (a) radiation, (b) convection, (c) evaporation, and (d) conduction.¹⁸ Minimizing heat loss through careful attention to the patient's environment is central to preventing hypothermia and its consequences. In theory, the prevention of hypothermia simply requires the elimination or minimization of heat loss by these four mechanisms. This primarily involves keeping the patient covered and dry. Warm air contains little heat (specific heat = 0.25 kcal/kg per °C) and is of little help in warming a cold patient. However, a warm air environment or warm air circulating blanket is an excellent way to prevent heat loss.

A considerable amount of energy and, therefore, oxygen is required to warm a hypothermic patient.^{18,19} The amount of energy required to warm a hypothermic patient by 3°C (34°C to 37°C, for example) is substantial and can be a significant metabolic stress. Based on the following formula, where specific heat of the human body is 0.83 kcal/kg per °C:

$$Q \text{ (heat)} = \text{mass (in kg)} \times 0.83 \text{ kcal/kg/}^{\circ}\text{C} \times [\text{Temp}_1 - \text{Temp}_2 (\Delta\text{Temp})]$$

$$Q \text{ (heat)} = 70 \text{ kg} \times 0.83 \text{ kcal/kg/}^{\circ}\text{C} \times [37^{\circ}\text{C} - 34^{\circ}\text{C}] = \mathbf{181 \text{ kcal}}$$

It will take 181 kcal of energy to return the patient to 37°C. A patient would have to double his or her oxygen consumption for 3 hours (or increase it by 50% for 6 hours) in order to generate this amount of heat. Patients in shock or recovering from shock are unable to meet such a high metabolic demand and should be actively warmed, rather than having to rely on their own metabolism (termed *passive warming*). A number of techniques for actively rewarming patients are available. These include overhead radiant heat warmers, whose effectiveness requires that they be placed relatively close to the patient (within 70 cm) and that the patient be fully exposed to the radiant heat, rather than covered by a blanket, in which case the blanket is warmed. Not surprisingly, risk of thermal injury is significant. Body cavity lavage (pleural or peritoneal) can potentially transfer large amounts of energy, but may not be practical in the multiply injured patient or due to the significant logistic challenges. Airway warming with heated, humidified oxygen transfers relatively little energy, similar to increasing ambient temperature in general, and should not be relied upon for treatment of hypothermia. The most effective method for rewarming is full cardiopulmonary bypass, which has been used successfully in severely hypothermic trauma victims. Although a heparin-bonded system avoids the need for systemic anticoagulation, limited availability and overall implementation technical challenges hamper its usefulness.^{20,21}

Other forms of extracorporeal rewarming of blood have been used and tested in hypothermic trauma patients. These include arteriovenous and venovenous bypass systems. Each uses a countercurrent exchange warmer; the advantage of the venovenous system is that it does not rely on the patient's blood pressure to maintain adequate flow, but it does require a more complex system than an arteriovenous system.^{22,23} Given the consequences of moderate to severe hypothermia, active rewarming should be used in any critically injured patient with a temperature of 34.5°C or below. Extracorporeal rewarming is the most effective option and radiant heat warmers are a secondary alternative. Although induced hypothermia increases survival after nontraumatic cardiac arrest, it should not be used in critically ill trauma patients.²⁴ Furthermore, induction of hypothermia has not been proven beneficial in the treatment of traumatic brain injury in either adults or children. Therefore, there are currently no circumstances where allowing a critically ill trauma patient to remain hypothermic is beneficial.

3 Hemostatic Abnormalities. Coagulopathies are common in critically injured trauma patients and their cause is multifactorial (Table 30.2). It is evident that hemorrhage accompanied by crystalloid and red blood cell transfusion results in dilution of coagulation factors, yet the implications of this dilution are not clear. Correlation between the amount of blood transfused and specific factor levels or the global measures of coagulation (activated partial thromboplastin time [aPTT], prothrombin time [PT]) are relatively low, and coagulopathy after non-trauma-related blood loss alone seems to generally occur after rather large transfusions (10 to 12 units of packed red blood cells).^{25,26} The effect of pure dilution on platelet counts is even less clear, with wide variations in the incidence of thrombocytopenia being reported. Basing coagulation factor replacement and platelet transfusion needs on predictive formulas is generally inaccurate.²⁷

A number of other factors have been linked to hemostatic abnormalities after trauma. Tissue trauma leads to platelet aggregation and activation of coagulation. Variable induction of these processes depending on the nature and severity of the trauma likely explain the lack of correlation of measured hemostatic deficits with blood loss, resuscitation, and blood transfusion volumes. For example, traumatic brain injury can result in coagulopathy that is independent of blood loss and transfusion volumes.²⁸ The exact mechanism is uncertain and likely more complicated than release of brain tissue thromboplastins, as has been previously theorized. Marked reductions in circulating fibrinogen concentrations (<50 mg/dL) are often seen, suggesting that hyperfibrinolysis plays an important role. Extremity injuries, including fractures and extensive soft tissue trauma, expose circulating coagulation factors and platelets to subendothelial collagen and tissue factor. However, clinically significant coagulopathies are unlikely to occur solely as the result of tissue trauma and require additional contributing factors. The effect of hypothermia on hemostasis is significant

TABLE 30.2**FACTORS CONTRIBUTING TO COAGULOPATHY IN TRAUMA**

Dilution of coagulation factors
Hypothermia (impaired enzyme activity, platelet dysfunction, enhanced fibrinolysis)
Acidosis
Tissue trauma (brain injury, fractures, soft tissue injuries)
Preexisting hemostatic defects (von Willebrand disease, hemophilia, chronic liver disease)
Medications (warfarin, antiplatelet agents)

and generally multifactorial, and is effectively reversed only by achieving normothermia and not with blood components.

In the event of severe hemorrhage and clinical evidence of coagulopathic bleeding, treatment must not wait for laboratory confirmation or for precise characterization of the defect(s). The development of diffuse hemorrhage intraoperatively, abnormal bleeding from intravenous sites, and marked bloody drain (thoracostomy, other surgically placed drains, etc.) output are obvious but late signs of a coagulopathy.

Review of the likely contributing factors will help direct appropriate blood component therapy while waiting for definitive laboratory diagnosis of the specific abnormalities. Laboratory characterization and treatment can be based on four tests: the platelet count, PT, aPTT, and fibrinogen levels. In most circumstances, a combination of platelet, plasma, and cryoprecipitate transfusions are required and are sufficient to treat hemostatic abnormalities after trauma. There are no definitive platelet count, aPTT, or PT thresholds that require treatment, but general recommendations follow. Isolated increases in the aPTT (normal PT) should not be treated with blood products as they are not due to deficiencies in the common pathway factors (X, V, II, and I). The results may be spurious (blood drawn through heparinized tube) or due to a lupus anticoagulant or hemophilia. In the initial postinjury period, platelet counts should be maintained above 50,000/ μ L in all cases, and above 100,000/ μ L in the presence of an injury with major hemorrhage (severe liver injury requiring packing, pelvis fracture with large hematoma, etc.) or when the consequence of ongoing bleeding is devastating, such as in the case of an intracranial hemorrhage, cerebral contusion, and possibly spinal fractures. Combined moderate abnormalities in the aPTT and PT (1.5 to 3.0 times the upper limit of normal) should be treated with 2 to 4 units of plasma. Marked elevations in PT and aPTT may reflect very low fibrinogen levels. In this case or when measured fibrinogen is less than or equal to 100 mg/dL, cryoprecipitate should also be given. A normal aPTT should be the target in patients with injuries that have resulted in major hemorrhage as indicated. In the presence of a traumatic intracranial bleed (epidural, subdural, or intracerebral hematoma), the risk for hemorrhage progression has been associated with the aPTT, but as there is no particular threshold where bleeding clearly increases, the treatment goal should be to maintain the aPTT within the normal range.²⁹

Recombinant factor VIIa has been used recently in severely coagulopathic trauma patients. Factor VIIa binds to tissue factor exposed at the site of injury and rapidly stimulates coagulation. Small studies have reported its usefulness in coagulopathic trauma patients who continue to bleed despite treatment with platelets, plasma, and cryoprecipitate.^{30–32} Factor VIIa also may be indicated in bleeding trauma patients who have been receiving warfarin and for the rare trauma patient with hemophilia A who also has factor VIII inhibitors.

Management of Traumatic Brain Injury and Intracranial Hypertension

Severely injured patients, particularly those who have sustained their injuries by a blunt mechanism, often have a traumatic brain injury (TBI) in addition to torso and extremity injuries.

- 4 The three principal challenges in the management of TBI are (a) avoiding secondary brain injury, (b) control of elevated intracranial pressure (ICP), and (c) early identification of any progression of mass lesions that would require surgical decompression. These issues are discussed in detail in the section devoted to trauma to the central nervous system. Management of patients with traumatic brain injuries requires the use of various monitoring and therapeutic strategies based on clinical course, computed tomography (CT) scan findings, and response to treatment. Significant deterioration in clinical course, physical examination, or ICP should be considered an absolute indication for

repeat CT scan. This is the only practical method for the prompt identification of patients in whom surgically correctable mass lesions develop during the initial phase of care.

Important additional and avoidable causes of secondary brain injury include hypotension, hyperthermia, seizure activity, hyperglycemia, and hypoxemia. Taken together, these contribute to deterioration in the severity of brain function and are often preventable. Hypotension at any point (even brief time periods) approximately doubles the likelihood of death from a given brain injury and must be avoided.^{33,34} Posttraumatic seizures increase cerebral metabolic rate, may increase ICP, and may cause important secondary brain injury. Prevention with intravenous phenytoin for the first 7 days after injury is indicated and effective.³⁵ Normocapnia (partial pressure of arterial carbon dioxide [PaCO₂] 35 to 40 mm Hg) should be maintained to avoid cerebral vasoconstriction and concomitant hyperfusion. However, brief, but not excessive, hyperventilation (keep PaCO₂ >25 mm Hg) as a temporizing measure to treat sudden increases in ICP or herniation may be necessary while preparing for definitive treatment (craniotomy, ventriculostomy for cerebrospinal fluid drainage, etc.).

Mechanical Ventilation

This will be discussed in more detail elsewhere, but there are a number of important considerations in the delivery of mechanical ventilation during this resuscitative and diagnostic phase. First, abnormal gas exchange, leading to hypoxemia, commonly exists in patients who are being resuscitated from hemorrhagic shock. Pulmonary edema may arise more as a consequence of overly aggressive crystalloid resuscitation than the transiently increased endothelial permeability consequent to shock. Transient hypoxemic respiratory failure is observed in trauma patients and may reflect a somewhat different pathophysiologic process than that which exists in the more prolonged hypoxemic respiratory failure seen with subsequent acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).³⁶ However, the goals of support at this point are primarily to ensure adequate resuscitation from shock, support oxygen delivery, and prevent any ongoing oxygen insufficiency. Therefore, it is important to distinguish the approach to mechanical ventilation in these first hours from the approach used once the patient has been successfully resuscitated and may have developed moderate to severe ALI. Initial ventilator settings aim to achieve adequate ventilation and oxygenation. This typically requires a minute ventilation of greater than or equal to 12 L/min and employs a fairly traditional approach. This includes volume-controlled ventilation, with a tidal volume of 8 to 10 mL/kg, a rate of 18 to 22 breaths/min, positive end-expiratory pressure (PEEP) of at least 5 to 10 cm H₂O, and a fraction of inspired oxygen (FiO₂) greater than or equal to 50%. Contrary to limits imposed for treatment of ALI or ARDS, it is appropriate to accept end-inspiratory static (P_{st}) pressures up to 40 cm H₂O and not aggressively limit tidal volume to 6 mL/kg and static pressures to less than 30 cm H₂O during this initial phase.

Rarely, circumstances occur in the severely injured patient that require unconventional ventilation strategies. These patients may be profoundly hypoxemic despite high FiO₂ concentrations and elevated PEEP and/or may have a massive air leak due to severe parenchymal or airway injury. These patients have typically received a massive volume of fluid during the acute resuscitation, have sustained severe thoracic trauma, and/or often both. There are no established proven best approaches to managing these patients. However, some principles can apply. First, large air leaks require treatment at this stage only if they are significantly affecting patient oxygenation due to diversion of the inspired gas away from gas-exchanging alveoli. Bronchoscopy should be considered to identify proximal airway injuries, but patient instability may preclude both bronchoscopy and definitive operative management. Therefore,

regardless of the anatomy of the injury, in these severely hypoxic patients, initial treatment options are often nonsurgical. Approaches include maneuvers to minimize air leak, such as high-frequency oscillatory ventilation (HFOV) and single-lung isolation (double-lumen endotracheal tube or bronchial blockers) to support effective gas exchange.

Abdominal Compartment Syndrome

- 5** Elevated intra-abdominal pressure (intra-abdominal hypertension) leading to pulmonary, renal, or cardiac dysfunction is termed the *abdominal compartment syndrome* (ACS). According to most studies, death is almost certain if greatly excessive pressure is not relieved.³⁷ Intra-abdominal hypertension can be defined as an intra-abdominal pressure of greater than or equal to 20 cm H₂O.³⁸ Experimental data indicate that hepatic arterial, portal venous, and hepatic microcirculatory blood flow are markedly reduced when intra-abdominal pressure is increased to greater than or equal to 20 cm H₂O.³⁹ Typically, it is observed after severe abdominal trauma that requires celiotomy and control of intra-abdominal hemorrhage.^{40,41} It has also been described in the setting of intra-abdominal injuries that were initially managed nonoperatively (e.g., severe liver or kidney injuries).⁴² In addition, excessive large-volume resuscitations, even in the absence of any direct abdominal trauma, can also lead to ACS.^{12,43,44}

The diagnosis often begins with a triad of clinical findings: (a) tense, distended abdomen; (b) increased end-inspiration airway pressures; and (c) oliguria despite appropriate volume resuscitation. Additional clinical measurements, particularly those that reflect poor cardiac performance, may be helpful in making the diagnosis. Signs consistent with ACS are a reduced cardiac output, elevated systemic vascular resistance, and elevated pulmonary capillary wedge pressure with simultaneous low or normal calculated estimates of end-diastolic volumes. The addition of corroborative findings from invasive hemodynamic monitoring may help clarify the diagnosis and direct the appropriate treatment.

Bladder pressure is the most widely used surrogate for intra-abdominal pressure. It is measured with the patient supine, by distending the bladder with 100 mL of sterile saline. The drainage tubing is then occluded, and an 18-gauge needle inserted sterily and connected to the pressure transducer through the aspiration port on the catheter tubing. An adequate pressure “tracing” is indicated by visible respiratory variation, which is usually less than 5 to 10 mm Hg.⁴⁵ The mean pressure should be used as an estimate of the intra-abdominal pressure, although this aspect of the procedure is not well characterized. A simpler method (although not validated) involves filling the bladder with 100 mL of sterile saline and elevating the clear tubing vertically above the pubic symphysis. The height of the fluid column is measured and converted to mm Hg (1.3 cm H₂O = 1 mm Hg).

Established ACS with associated organ dysfunction is treated with surgical decompression of the abdomen.³⁸ In contrast, elevated intra-abdominal pressures, regardless of the actual measured value, in the absence of physiologic derangement is not an indication for decompressive celiotomy. Similarly, high intrathoracic pressures and marked FiO₂ and PEEP requirements are not necessarily sufficient to warrant decompression. Progressive renal dysfunction (oliguria, rising creatinine) despite adequate preload and ongoing resuscitation should warrant abdominal decompression. Persistent shock, particularly when vasopressor agents are needed to supplement fluid resuscitation, also warrants decompressive celiotomy. There are no absolute thresholds for airway pressure, urine output, or arterial blood lactate that indicate or contraindicate decompressive celiotomy. Of note, ACS can occur in patients whose fascia has not been definitively closed, but where some other technique of temporary abdominal closure has been performed and is sufficient to generate excessive

intra-abdominal pressures. One causal factor that seems common to all cases of ACS is the use of very aggressive crystalloid resuscitation, including attempts to reach elevated O₂ delivery to reverse a perceived oxygen debt. Therefore, attempts to achieve “supranormal” endpoints (cardiac index of ≥ 4 L/min per m² or oxygen delivery index of ≥ 600 mL/min per m²), which often require the excessive resuscitation volumes that contribute to ACS, should be avoided.¹¹

ORGAN SYSTEM SUPPORT AND DEFINITIVE CARE (1 TO 7 DAYS POSTINJURY)

Coordinating Multidisciplinary Care and the Timing of Operative Interventions

Decisions made during this phase will significantly influence patient outcome, and this period should not simply be considered a period of observation and general support. During and following resuscitation, patients require careful reevaluation as part of a tertiary survey to establish subsequent priorities in care. Communicating with other specialties to determine the timing of additional diagnostic tests and operative procedures is crucial during the first week after injury. It is typically the role of the general surgeon or surgical intensivist to oversee and coordinate the timing of subsequent surgical care. The definitive care of fractures and non-life-threatening torso injuries should be delayed when patients are hemodynamically unstable, acidotic, hypothermic, or coagulopathic or have intracranial hypertension.⁴⁶ Once these are addressed and corrected (typically within 48 hours), definitive repair can be undertaken. Generally, the more delayed operative stabilization of fractures, such as femoral, spine, and pelvic, is associated with an increased risk of respiratory complications.^{47,48} On the other hand, it is important not to risk worsening organ function, particularly respiratory failure and TBI, by exposing patients to prolonged operative procedures and concomitant blood loss and potential hypotension at a time when they are least able to tolerate an additional physiologic challenge. Rather than the absolute timing of definitive procedures, it appears that the duration of the operation and the associated physiologic stress are the most important factors in determining how well the patient tolerates the intervention.^{46,49} It is important, therefore, to discuss the details and expected course of each operative procedure with the consultant surgeon.

Mechanical Ventilation and Acute Respiratory Failure

Within 24 to 48 hours, many severely injured patients can be rapidly liberated from mechanical ventilation, are able to adequately protect their airway, and can be extubated. Prompt recognition of when the patient is ready to be liberated from mechanical ventilation can be best accomplished by performing a trial of spontaneous breathing rather than relying on any single measure (or even a combination of measures) of respiratory muscle strength or endurance.^{50,51} Many patients require more prolonged mechanical ventilation, either for respiratory failure or often because they are unable to protect their airway, particularly in cases of TBI. In some cases, mechanical ventilation is supportive, gas exchange is not particularly impaired, and the lung fields on chest radiography are relatively normal. In these circumstances, mandatory volume-controlled (also termed “assist-control”) ventilation aimed to maintain the partial pressure of arterial oxygen (PaO₂) at 80 to 100 mm Hg and the PaCO₂ at 35 to 45 mm Hg is appropriate. This can be accomplished using tidal volumes of 8 to 10 mL/kg of predicted body

weight, positive end-inspiratory pressure of 5 to 10 cm H₂O, an FiO₂ of 40% to 60%, and a respiratory rate of 12 to 24 breaths/min. Slight adjustments above or below any of these thresholds are acceptable to achieve these targets. There is no proven advantage to using any other mode or technique of delivering positive-pressure ventilation.

- 6** Severe ALI and ARDS develop in a substantial fraction of critically ill trauma patients and contribute to prolonged and costly ICU care.^{4,52} ALI is defined by the following set of clinical criteria: (a) diffuse patchy pulmonary infiltrates on chest radiograph, (b) PaO₂/FiO₂ less than or equal to 300, and (c) cardiac failure excluded as a cause for pulmonary edema; ARDS is defined by the same criteria except for a PaO₂/FiO₂ less than or equal to 200. While the pathophysiology is not entirely clear, an intense alveolar inflammatory response that correlates with the severity of the initial insult exists in these patients that may be influenced by positive-pressure ventilation, based on the following^{53–55}: first, alveolar edema can be reduced by preventing end-expiratory collapse with sufficient PEEP.⁵⁶ Second, a marked inflammatory response can be induced in otherwise normal lungs in experimental animals exposed to positive-pressure ventilation, particularly when alveoli are allowed to repeatedly collapse (0 cm H₂O PEEP) and repeatedly overexpand with each inspiratory cycle.⁵⁷ Third, a similar inflammatory response is seen in patients with ARDS, and this inflammatory response can be reduced by a strategy that reduces end-expiratory collapse and end-inspiratory distention.⁵⁵ In clinical trials, mortality was reduced when patients were treated with protocols designed to limit alveolar stretch using a tidal volume of 6 mL/kg compared to subjects ventilated with higher tidal volumes (~12 mL/kg).^{58,59} These trials included patients with ALI and ARDS due to many different risk factors, including trauma and massive transfusion. This approach is therefore applicable and considered the standard of care for trauma patients with ALI and ARDS. Judicious use of PEEP to maintain moderate FiO₂ levels (≤60%) should typically be employed. An acceptable approach is based on PEEP and FiO₂ combinations used by the ARDS Network.⁵⁸ There is no benefit to using relatively higher or lower levels of PEEP or FiO₂ to achieve levels of PaO₂ greater than 80 to 90 in these patients.⁶⁰

Nutritional and Metabolic Support

Nutritional and metabolic support is an important but often neglected component of caring for critically injured patients. Once resuscitation from shock is complete, a hypermetabolic and hyperdynamic cardiovascular response ensues, which has features characteristic of the more general acute-phase response, frequently referred to as systemic inflammatory response syndrome (SIRS). Important changes include increased energy expenditure and protein breakdown with a shift in metabolic priorities to favor the production of proteins characterized as acute-phase reactants, produced primarily by the liver.⁶¹ Although the initial injury and subsequent complications are the prime drivers, the type and timing of nutritional and metabolic support are important modifiers of this response and can help reduce the loss of nitrogen derived from structural protein catabolism.

The route of administration, timing, amount, and nutrient composition of nutritional support are of particular relevance to critically injured patients. When compared to total parenteral nutrition (TPN), enteral nutrition (EN) is associated with greater constitutive protein concentrations (prealbumin and albumin) and lower acute-phase reactant proteins (such as C-reactive protein) in the initial days after trauma. These effects may be due to a direct effect of the route of nutrient delivery or to an associated reduction in infectious complications seen with EN.⁶² Therefore, nutritional support should be delivered enterally when possible. Small randomized clinical trials and subsequent meta-analyses have shown that enteral

nutrition results in fewer nosocomial infections than parenteral nutrition. The evidence is more complete in patients with severe torso trauma, but can be generalized to those with severe extremity injuries.^{63,64}

Starting EN within the first 48 hours of injury appears beneficial. However, it is first important to ensure that the patient has been fully resuscitated, as intestinal ischemia may be the result of feeding a patient with splanchnic hypoperfusion due to ongoing hypovolemia. This may also lead to intolerance, gastroparesis, and aspiration. There is no proven definitive advantage of a very aggressive approach to feeding (6 to 12 hours after injury) when compared to EN delayed until 48 to 72 hours after injury. Nevertheless, it has been demonstrated that starting EN within 12 hours of being resuscitated from shock is safe and tolerated by approximately 80% of patients when a defined protocol for EN is used.⁶⁵

The amount and composition of nutritional support, whether delivered enterally or parenterally, can be estimated or directly measured and the metabolic response to this support should be monitored. Caloric requirement estimates are derived from the Harris-Benedict equation in which basal energy expenditure (BEE) and, thus, caloric needs are calculated from an equation based on the patient's age, height, weight, and gender. The equations are as follows:

$$\text{Females: BEE} = 655 + 9.7 (\text{wt in kg}) + 1.8 (\text{ht in cm}) - 4.7 (\text{age})$$

$$\text{Males: BEE} = 66 + 13.75 (\text{wt in kg}) + 5 (\text{ht in cm}) - 6.8 (\text{age})$$

Depending on the severity of injury, the BEE expenditure is multiplied by a “stress” factor that estimates the energy expenditure above basal requirements. On average, this factor is approximately 1.4. Caloric needs according to this formula are approximately 25 to 30 kcal/kg per day. Head-injured patients typically have higher energy expenditure than other trauma patients (140% BEE), whereas spinal cord-injured patients often have lower metabolic demands (94% BEE). It is reasonable to estimate the initial caloric requirements using the Harris-Benedict equation, but when critical illness is prolonged beyond 7 to 10 days, direct measurements should be used to determine energy expenditure and refine nutritional support. Metabolism consumes oxygen and produces carbon dioxide. Therefore, oxygen consumption (VO₂) and carbon dioxide production (VCO₂) can be used to calculate caloric needs using the abbreviated de Weir equation: $EE = 1.44 \times [(3.9 \times VO_2) + (1.1 \times VCO_2)]$. Measuring VCO₂ requires a metabolic cart and is often inaccurate when FiO₂ requirements are high.

Although protein calories are included in the estimated caloric requirements, it is hoped that delivered protein is not broken down as an energy source, but rather used as a source of amino acids. Protein or nitrogen requirements are generally estimated relative to caloric goals. A kilocalorie/nitrogen (mg) ratio of 100:1 is considered appropriate for critically injured, catabolic patients. Elemental formulas may be better tolerated in patients who have been without EN for more than a few days, although there is no definitive advantage over nonelemental ones. The use of “immune-enhancing” formulas, in which additional amino acids such as arginine, omega-3 fatty acids, and various antioxidants are added, is controversial. The anti-inflammatory effects of omega-3 fatty acids are the most promising, and these nutrients seem beneficial in critically ill patients.⁶⁶ Similarly, the addition of antioxidants (selenium, vitamin C, and vitamin E) delivered enterally or intravenously and started early in the postinjury phase may reduce postinjury organ failure.⁶⁷

Prevention of Gastric Stress Ulcer Hemorrhage

The incidence of clinically relevant stress ulceration or gastritis has substantially dropped. Whether this is a function of overall

better general supportive care, particularly adequate resuscitation, or due to specific preventative measures is uncertain. Nevertheless, trauma patients in the ICU receiving mechanical ventilation for over 48 to 72 hours constitute a high-risk group in whom the risk for upper gastrointestinal hemorrhage is reported to be from 4% to 12%.^{68,69} Histamine-2-receptor antagonists may be the most effective agent for preventing upper gastrointestinal hemorrhage in the ICU, and many practitioners choose them for prophylaxis.^{70,71} However, nosocomial pneumonia and, in trauma patients, other nosocomial infections as well are increased in patients receiving histamine-2 antagonists when compared to those given sucralfate.^{72,73} The use of sucralfate avoids gastric acid neutralization and the potential systemic effects of histamine-2-receptor antagonists. Proton pump inhibitors markedly suppress gastric acid secretion but are no more effective than other agents in reducing clinically relevant hemorrhage from stress gastritis. Once enteral nutrition via the stomach has been initiated and shown to be tolerated, there is no proven benefit to continuing any of the gastric-protective interventions.

Pain Relief

Approaches to pain relief and sedation assume great importance in this phase of care of the critically ill trauma patient. In particular, adequate pharmacologic relief of thoracic pain due to multiple rib fractures may be critical to avoiding intubation and to hastening liberation from mechanical ventilation and extubation. It appears that, when possible, thoracic epidural analgesia results in fewer cases of nosocomial pneumonia and fewer days of mechanical ventilation than systemically administered opioid analgesia.⁷⁴ Given the multiple painful stimuli experienced by trauma patients in the ICU (fractures, surgical incisions, lacerations, contusions, etc.), it is reasonable to consider regional analgesia not just for those with multiple rib fractures. However, contraindications to the use of epidural analgesia are commonly encountered and include severe traumatic brain injury, spinal fracture, coagulopathy, or any injury that would preclude appropriate positioning for accessing the epidural space. While sedation is critical to optimize patient rest and recovery, overdosing and deposition of active byproducts can lead to prolonged oversedation and inability to extubate in a timely fashion. All patients receiving sedation should undergo a “sedation holiday” every 24 hours, allowing the patient to return to baseline mentation and permit serial daily monitoring of overall neurologic status.

Venous Thromboembolic Disease

- 7 Venous thromboembolic disease (VTE), which can manifest as deep venous thrombosis (DVT) or pulmonary embolism (PE), is common after trauma and can have serious or fatal consequences. Pulmonary embolism is the most devastating manifestation and an important cause of posttraumatic death. Both can occur at any time after injury, and many occur as early as the initial 48 hours.⁷⁵ In particular, spinal cord injuries and lower extremity and severe pelvic fractures are strong risk factors for VTE.⁷⁶ However, patients without these injuries are also at risk for thromboembolic complications. Other important risk factors include increasing age, immobility, and the need for blood transfusions.^{76,77} That most trauma patients are at risk and that both DVT and PE can occur early pose difficult practical problems to apply effective prevention strategies due to the high risk for ongoing or secondary bleeding and associated complications.

Low-molecular-weight heparin is more effective than unfractionated heparin for prophylaxis and should be used in patients in high-risk groups. One large randomized trial demonstrated that proximal DVT risk was approximately 30% lower in patients receiving low-molecular-weight heparin (30 mg twice

daily) than in those receiving unfractionated heparin (5000 IU twice daily).^{76,78} However, the risk of bleeding may be higher when patients are given low-molecular-weight heparin, and it is not recommended for use in those with intracranial hemorrhage or ongoing extracranial bleeding. Alternative prophylactic methods exist to address the risk of DVT in patients who cannot receive prophylactic or therapeutic heparin. Intermittent pneumatic compression devices can be used in patients with contraindications to heparin prophylaxis. Although once thought that these devices increased local and regional fibrinolysis by increasing tissue factor pathway inhibitor and decreasing plasminogen activator inhibitor activities, recent evidence suggests that this is not the case. Any benefit from pneumatic compression is likely due to improved venous blood flow.^{79,80} In addition, prophylactic placement of a vena cava filter (VCF) is appropriate for patients at high risk for VTE who cannot receive prophylactic anticoagulation.⁸¹ This has become an increasingly acceptable alternative with the development of retrievable filters.⁸² Alternatively, sonographic screening, followed by VCF placement in only those with documented DVT, can be used in patients with a contraindication to prophylactic and therapeutic anticoagulation.⁸³ VTE prophylaxis is considered standard trauma care and should be approached with a specific protocol to ensure that all patients receive appropriate management.⁸⁴

MANAGEMENT OF INFECTIOUS COMPLICATIONS (8 DAYS AND BEYOND)

Infectious complications can occur earlier in the postinjury period, but they assume heightened importance as patients remain in the ICU beyond the first week. At this point, prevention, surveillance, rapid diagnosis, and effective treatment become an important focus of the critical care team.

Nosocomial Pneumonia

- 8 Pneumonia is the most common pulmonary complication and the most common infection in trauma victims. It most often occurs in association with tracheal intubation, and when associated with mechanical ventilation is referred to as ventilator-associated pneumonia (VAP). Posttraumatic VAP occurs due to a combination of factors including alterations in host defense mechanisms and concomitant colonization with pathogenic bacteria. Taken together, recumbent positioning and translaryngeal intubation facilitate microaspiration of secretions that have pooled in the hypopharynx. Although gastric bacterial colonization may lead to oropharyngeal and tracheal colonization, oropharyngeal colonization frequently precedes both gastric and tracheal colonization.⁶⁹ Alterations in host innate immune mechanisms likely contribute to the risk for pneumonia by impairing cellular immune responses to aspirated bacteria. Examples of alterations in host innate immune mechanisms that exist in critically ill patients include reductions in immune cell expression of bacterial antigen receptors (Toll-like receptors 2 and 4) and alterations in intracellular signalling (decreased nuclear factor- κ B heterodimer formation) leading to reduced cytokine responses.^{85,86}

Posttraumatic nosocomial pneumonia is caused by a range of gram-negative and gram-positive organisms. *Pseudomonas* species and *Staphylococcus aureus* are the two most common pathogens and together are responsible for up to 40% of cases.^{87,88} Multidrug-resistant bacteria are becoming a greater challenge. Both gram-negative organisms, such as *Acinetobacter* species, and gram-positive organisms, such as methicillin and vancomycin-resistant staphylococci and enterococci, have emerged as important pathogens.

Prevention strategies reduce the incidence of VAP. For example, elevating the head of the bed to 45 degrees effectively

reduces VAP, presumably by minimizing gastroesophageal reflux and pooling in the hypopharynx with microaspiration.⁸⁹ This is the single most important preventative strategy, but may not be possible in certain circumstances. It may be contraindicated in patients with vertebral, spinal cord, or pelvic injuries. Various strategies to eradicate potential pathogens from the patient's gastrointestinal tract have also been tested. While aimed at reducing all types of infectious complications, their effect on nosocomial pneumonia may be most pronounced because this is the most common infection. These strategies have been typically referred to as selective digestive decontamination (SDD) or selective oropharyngeal decontamination (SOD), when applied in a more limited manner.⁹⁰ Despite being the subject of many clinical trials and meta-analyses, the effectiveness of SDD is controversial and it has not gained widespread use.⁹¹ However, a large clinical trial has demonstrated a reduction in mortality when SDD was applied to critically ill patients expected to have a high risk of mortality.⁹² In trauma patients, SDD appears to reduce the number of infections but not fatality rates.⁹³

The diagnosis and treatment of VAP is ideally based on direct sampling and quantitative cultures of distal pulmonary secretions, typically with bronchoscopic guidance. Bronchoscopy is most useful in patients with specific clinical factors suggesting they have pneumonia. These factors are leukocytosis, fever, purulent tracheal secretions, and persistent or progressive pulmonary infiltrates on chest radiography. While not sufficient to diagnose VAP, these criteria should prompt bronchoscopic sampling for quantitative cultures, which can be obtained from bronchoalveolar lavage (BAL) or with a protected specimen brush (PSB). The threshold for diagnosis of pneumonia is greater than or equal to 10^4 colony-forming units/mL based on BAL samples and greater than or equal to 10^3 colony-forming units/mL based on PSB samples. A clinical approach using bronchoscopically obtained specimens leads to more appropriate use of antibiotics, shorter ICU stays, and lower mortality in patients with pneumonia, including trauma patients.⁹⁴

Treatment initially is empiric and must be started immediately to minimize mortality; antibiotic choice depends on initial Gram stain identification of predominant organisms and the knowledge of prevailing antibiotic sensitivities of organisms specific to the unit or hospital. Once the organism and specific antibiotic sensitivities are identified, treatment should be modified accordingly ("de-escalation") using the most appropriate antibiotic or combination for the specific organisms. The duration of antibiotic therapy is controversial. An inadequate duration of treatment may increase the risk for recurrent VAP with resistant organisms, whereas excessive treatment is costly, may result in the selection of other resistant organisms, and does not seem to improve outcome. Generally, antibiotic treatment for 8 days, assuming adequate initial treatment, is as effective as a 15-day course of treatment. However, for VAP caused by non-lactose-fermenting gram-negative rods (e.g., *Acinetobacter* and *Pseudomonas*), a 15-day course results in lower recurrence.⁸⁸ Treatment failure with these organisms is common and associated with higher mortality. The two most important factors associated with treatment failure and poor outcomes are delayed or inadequate initial antibiotic therapy,⁹⁵ both of which may occur in up to 34% of cases.⁹⁶ This can be prevented by following the approach indicated earlier. However, even in the presence of timely and appropriate antibiotic therapy, treatment failure occurs and is correlated with the initial severity of illness based on Acute Physiology and Chronic Health Evaluation (APACHE) II scores and comorbidities.⁹⁶

Vascular Catheter-related Infections

Intravascular catheters are an important source of nosocomial infections. These infections can be classified as primary bloodstream infections, catheter-related bloodstream infections (in

which cultures of the blood and of the catheter reveal the same pathogen), and exit site infections (in which there is local catheter site evidence of infection without positive blood or catheter cultures).⁹⁷ Approximately 10% of critically ill patients will develop a vascular catheter-related infection during their ICU stay, and this translates into approximately 9 infections per 1,000 patient-days.⁹⁷ In the absence of infection at the site of insertion, the diagnosis of catheter-related infections is difficult. Options for diagnosing catheter-related infections include culture of a catheter segment or of blood drawn through the catheter alone or simultaneously with blood drawn from a peripheral vein. These specimens can be quantitatively, semiquantitatively, or qualitatively cultured. In general, quantitative catheter segment cultures are the most accurate (highest combined sensitivity and specificity) for the diagnosis of infection. Unpaired quantitative culture of blood (drawn via the vascular catheter alone, without paired peripheral samples) is slightly less accurate.⁹⁸ Therefore, when infection is suspected but the insertion site is not inflamed or draining, the catheter should be removed for intratissue catheter segmental culture or blood should be drawn from the catheter for quantitative culture.⁹⁸

Preventative strategies can lower the incidence of catheter-related infections in the ICU. Full sterile barriers are appropriate for insertion of central venous catheters and reduce subsequent infection rates, but they may not be required for the insertion of peripheral arterial catheters.^{99,100} Chlorhexidine gluconate results in fewer bloodstream infections in comparison to povidone-iodine when used for insertion site preparation.¹⁰¹ Using a silver-impregnated antimicrobial subcutaneous cuff attached to central venous catheters or antibiotic-impregnated catheters decreases the incidence of catheter infections. However, while impregnating catheters with antimicrobials (rifampin-minocycline) may reduce the risk of catheter-related infections, antibiotic resistance can develop.

Hyperglycemia does not seem to be an important risk factor for catheter-related infections. However, TPN administration is a risk factor for catheter-related and other bloodstream infections. Avoiding unneeded TPN use and preventing even short periods of excessive caloric intake will help reduce the incidence of these infections.^{102,103}

Other Infections

Other infections are less common in trauma patients but are still of considerable importance and reflect the spectrum of infections seen in other cohorts of critically ill patients. Wound and urinary tract infections, intra-abdominal abscesses, and less commonly considered complications such as *Clostridium difficile* colitis and acalculous cholecystitis must be considered in the days to weeks after injury. Any patient developing diarrhea or a rapidly rising white blood cell count, particularly following or during a course of antibiotic therapy, should have a stool specimen sent for *C. difficile* toxin and, in the critically ill, metronidazole begun empirically.

Fungal infections are uncommon but are serious complications in critically ill trauma victims. They typically develop after a prolonged ICU course in patients who have received multiple antibiotics for nosocomial bacterial infections. They are responsible for 5% to 17% of bloodstream infections in critically ill patients and various *Candida* species are responsible for the majority of these infections.^{104–106} Candidemia refers to the growth of *Candida* from blood cultures, and systemic candidiasis refers to the situation in which microabscesses are present in multiple organs and tissues and are extremely difficult to eradicate.

The single most relevant risk factor for the development of candidemia in nonneutropenic trauma patients is the use of broad-spectrum antibiotics. Colonization with *Candida* organisms is another important risk factor that can be useful in identifying the highest-risk patients.^{105,107} Fungal infections acquired

in the ICU are an important risk factor for death in critically ill patients in general as well as in trauma patients.¹⁰⁴ Although antifungal prophylaxis with fluconazole seems safe and may reduce the incidence of invasive fungal infections in high-risk surgical patients, it is typically not indicated in trauma patients.¹⁰⁷ The diagnosis of candidemia is challenging, and the clinical presentation is neither sensitive nor specific for fungal infection. However, invasive *Candida* infections can occur without cultures being positive. Therefore, treatment is often empiric, based on a high clinical suspicion, typically in a patient colonized by *Candida* with sepsis who is not responding to antibiotic therapy. Treatment is generally with fluconazole or another azole antifungal agent. *Candida glabrata* and *Candida krusei* should be considered resistant to fluconazole, and resistance to amphotericin has been documented to occur.¹⁰⁸ Therefore, if these organisms are suspected or determined to be responsible for infection, amphotericin or one of the agents in the echinocandin class should be used as initial therapy. Voriconazole is a newer azole antifungal that is effective against azole-resistant *Candida* species. It is an acceptable alternative to amphotericin and the echinocandins.^{109,110}

CHAPTER 31 ■ ENVIRONMENTAL INJURIES

GREGORY J. JURKOVICH

KEY POINTS

- 1 Of 3,000 species of snakes worldwide, only 375 are venomous, with approximately 20 deaths per year in the United States caused by snakebites compared with 100,000 species of Hymenoptera that cause approximately 40 deaths per year, mostly as a result of severe anaphylactic reactions.
- 2 Snakebite morbidity is a result of venom composition, time of year, size of snake, and depth and amount of envenomation. Venoms consist of numerous (up to 30 or more) proteins that disrupt endothelial cells and blood flow, produce neuromuscular blockade, or generate a coagulopathy via procoagulants. Coral snake venom also has direct neurotoxins and cardiotoxins.
- 3 Snakebites induce immediate pain, edema, and erythema at the site, and spread at greater than 30 cm/h indicates severe envenomation. Initial incision and suction provides little benefit, as does a proximal tourniquet, which may cause harm. Use of purified ovine antivenin is effective and has replaced equine antivenin with its associated risk of serum sickness.
- 4 Spider bites produce toxicity by local tissue necrosis (brown recluse and hobo spiders) and painful muscle contractions (black widow spider) in the United States. Deaths may be caused by stinging Hymenoptera, including bees (particularly aggressive Africanized bees), fire ants, and scorpions.
- 5 Hypothermia risk is high in the severely injured patient as a result of exposure, loss of normal protective metabolism (i.e., shivering), rapid massive infusion of cold fluids/blood, and open thoracic and abdominal cavities.
- 6 Loss of protective responses to hypothermia occurs between 33°C and 30°C with an initial intensive sympathetic-type reaction with tremulousness, profound vasoconstriction, tremendous increases in oxygen consumption, and accelerated heart rate and minute ventilation.
- 7 Hypothermia affects both blood gases and coagulation parameters with increased PAO₂ and decreased PCO₂, whereas coagulopathy is aggravated as a result of platelet dysfunction and impaired enzyme activity. However, both blood gases and coagulation parameters should be assessed at 37°C because if the arterial blood gas value is normal at 37°C, it will be acceptable at lower temperatures, whereas coagulopathy at 37°C requires blood component therapy separate from warming to correct the cold-induced coagulopathy.
- 8 Hypothermia increases risk of mortality at every level of injury. And, although hypothermia delays mortality in experimental shock models, there is no improvement in outcome when applied to severe traumatic brain injury, and patients rapidly rewarmed require less resuscitation volume and have improved survival.
- 9 Hypothermia is treated either passively by preventing further losses and allowing endogenous rewarming or actively either externally by use of warm blankets, heating pads, or lights and immersion in warm water or internally by core rewarming, which includes heated intravenous fluids; heated peritoneal, thoracic, gastric, bladder, or colonic lavage; heated moist inhaled air; extracorporeal circulatory rewarming (continuous arteriovenous rewarming), or closed circuit intravascular countercurrent heat exchange devices.
- 10 Frostbite involves ice crystal formation and unpredictable loss of tissue. Early definitive rewarming (avoiding refreezing) by submersion in 40°C to 42°C water is preferable with subsequent meticulous care, possible early thrombolytic therapy, and awaiting demarcation and avoidance of early débridement to optimize outcomes and tissue salvage.

ENVENOMATION

Snakes and Snakebites

- 1 There are more than 3,000 species of snakes worldwide, of which approximately 375 are venomous. Although estimates vary greatly, possibly 300,000 venomous bites each year are responsible for 30,000 deaths annually worldwide. In the United States, an estimated 45,000 snakebites occur annually, of which 7,000 are from venomous snakes, resulting in 14 to 20 deaths each year.¹⁻⁴ The American Association of Poison Control Centers provides an annual report of snakebites that are reported to poison centers in the United States; this information can be accessed at <http://www.aapcc.org/>. It is likely that many snakebites go unreported. For example, in 2007 only three deaths due to bites and stings from all sources were reported. A recent review of all human rattlesnake bites from 1993 to 2007 published in the Annual Reports of the American Association of Poison Control Centers revealed that while the

incidence of severe (reported) bites is decreasing by 2% per year, annual rates of fatalities showed no significant change from 1983 through 2007.^{4a}

From 2001 through 2005 there were 23,676 human exposures (average = 4,735/year) to native venomous snakes in the United States reported to U.S. poison centers in all states except Hawaii: 98% were to viper (Crotalidae) snakes and 2% to elapids. Overall, 77% of victims were male, 70% were adults older than 20 years, 12% were aged younger than 10 years, and interestingly, 65 cases involved pregnant women. The overall hospital admission rate was 53%. Outcomes were generally more severe with rattlesnake and copperhead envenomations and in children younger than 6 years of age. The fatality rate of reported cases was 0.06%.^{4b}

The five main families of poisonous snakes found worldwide are the Colubridae, Elapidae, Hydrophiidae, Viperidae, and Crotalidae. The Colubridae family consists primarily of the boomslang and the bird snake, which are mainly found in Africa. The Elapidae family includes the cobras, the coral snakes, and the adders, which are found throughout Asia, Africa, the Americas,

TABLE 31.1**SNAKES OF THE FAMILY CROTALIDAE**

■ GENUS	■ COMMON NAME	■ CHARACTERISTICS	■ RANGE
Agkistrodon	Water moccasin and copperhead	No rattles; large plates on crown	North America, southeastern Europe, Asia
Bothrops	New World pit vipers	No rattles; small scales on crown; large scales on ventral tail	Mexico to South America
Crotalus	Rattlesnakes	Rattles; small scales on crown	North, Central, and South America
Lachesis	Bushmaster	No rattles; small scales on crown; small scales on ventral tail	Central and South America
Sistrurus	Massasaugas and pygmy	Rattles; large plates on crown	North America
Trimeresurus	Rattlesnakes	No rattles; small scales on crown	Asia

and Australia. The Hydrophiidae family consists of the sea snakes, which are found throughout the Pacific and along the west coast of South America. The Viperidae family consists of Old World vipers, which are found throughout Africa, Europe, and the Middle East, and are noted by their lack of a heat-sensing pit. The Crotalidae are the true pit vipers and are found worldwide. Some classification systems note the pit vipers as a subfamily of the Viperidae.⁵

The native venomous snakes of North America are members of the phylum Chordata, class Reptilia, order Squamata, suborder Serpentes, and the two families Crotalidae and Elapidae (Table 31.1).

Rattlesnakes are members of the family Crotalidae and the genus *Crotalus* or *Sistrurus*. Water moccasins (or cottonmouths) and copperheads are also members of the Crotalidae family, but of the genus *Agkistrodon*. The coral snake is the major representative of the Elapidae family and of the genus *Micrurus* or *Micruroides*. Other well-known members of the Elapidae family that are not indigenous to North America are the cobras and mambas. The distribution of venomous snakes in the United States is extensive, with at least one native species found in every state except Maine, Alaska, and Hawaii. Rattlesnakes are particularly widely distributed, whereas the water moccasin is found in the southeastern United States, Mississippi Valley, Illinois, and Indiana. The copperhead's range is primarily from central Massachusetts to northern Florida and west to Illinois and Texas.

The Crotalidae, or pit vipers, have a number of characteristics that help distinguish them from benign snakes (Fig. 31.1). Their unique and characteristic thermoreceptor “pit” is an infrared sensor located between the nostril and the eye that helps the snake localize its prey. Pit vipers also have a vertical elliptical pupil, a triangular head, and retractable fangs. Venomous snakes have a single row of plates distal to the anal plate on their ventral surface, whereas harmless snakes have a double row of caudal plates.

Coloration is so variable that it is nearly useless as a distinguishing characteristic. An exception is the coloration of the Elapidae coral snake, which can be identified by the simple rhyme, “Red on yellow kill a fellow; red on black venom lack.” Coral snakes have circular bands of colors with red adjacent to yellow, whereas the nonvenomous but similar-looking king snake has red on black bands that do not completely encircle it. The eastern coral snake has a completely black nose, whereas the king snake usually does not.

Most snakebites in the United States occur in the Sunbelt region between April and October, with the peak incidence occurring in the summer months of July and August. Prehibernation and posthibernation snakes appear to be more aggressive. The victims of snakebites are typically men between 18 and 50 years of age. Up to 60% of snakebite victims are delib-

erately handling snakes,⁶ and alcohol consumption in snakebite victims is common.⁷

Not every poisonous snakebite results in envenomation, and even the presence of fang marks does not necessarily correlate with envenomation. Venom is produced in Duvernoy glands, which are located on the dorsal sides of the head and correspond to the parotid glands. The location of this large gland gives the head its characteristic triangular shape. During the bite, the venom is forced through the hollow fangs by the palatine muscles and extruded out the orifices, which are located just proximal to the tip. Therefore, clothing, gloves, and shoes may significantly diminish the depth of penetration and limit the amount of envenomation.

2 The severity of envenomation is related to the amount of venom injected, the concentration of the venom, and the size of the snake. Direct intravenous envenomation is unusual but particularly severe.⁸ Snakebites with a distance between the fangs of more than 15 mm are representative of a large snake and therefore suggest a potentially more significant envenomation. Hibernation also seems to play a role in severity. After hibernation, snakes are relatively dehydrated because they have been in a prolonged fasting state, and therefore they produce a more potent, concentrated venom. The degree of envenomation also varies because 10% to 25% of bites have no significant envenomation, even when fang marks are noted on the victim. With each strike, the snake may discharge between 25% and 75% of its venom, so that successive or repetitive strikes tend to diminish the amount of venom available. Snakes that are angered or fearful may discharge greater amounts of venom. Table 31.2 lists the grading scale for pit viper bites.^{24–28}

Snake Venom. The function of venom is to kill or immobilize prey and to aid in digestion. Venom consists of a complex array of proteins and enzymes that have historically been characterized as neurotoxins, hemotoxins, and cardiotoxins.⁹ The components of pit viper venom, however, affect almost every organ system; thus, labeling snake venom as a specific organ toxin is probably inaccurate.⁵ More than 26 different proteins and nonenzymatic peptides have been isolated from various venoms.^{2,5} The Crotalidae venom consists of approximately 90% water, 5 to 15 enzymes, 3 to 12 nonenzymatic proteins and peptides, and more than 6 other unidentified substances. A partial list of these enzymes is shown in Table 31.3 and includes several proteolytic enzymes, phospholipase, nucleotidase, acetylcholinesterase, and amino acid oxidase.

These low-molecular-weight peptides and polypeptides (6 to 100 kD) appear to act by damaging vascular endothelial cells. Electron microscopic analysis of tissue from human snakebite victims has demonstrated disruption of the vascular endothelium and other plasma membranes. Microangiopathic vascular injury leads to increased permeability, peripheral

Poisonous (pit vipers)

Harmless

FIGURE 31.1. Characteristics of snakes that differentiate poisonous pit vipers from harmless snakes.

TABLE 31.2 **CLASSIFICATION**

GRADING OF PIT VIPER BITES

GRADE	DESCRIPTION OF BITE
0	Visible bite but no envenomation; swelling/erythema around the fang mark <2.5 cm; minimal pain and tenderness; no systemic symptoms
I	History of immediate pain with bite; swelling and erythema 5–15 cm from fang marks; no systemic signs or symptoms
II	Moderate pain; erythema and edema of 15–40 cm; mild systemic signs such as weakness and emesis; may have abnormal laboratory findings
III	Severe pain; erythema and edema >40 cm, with petechiae and bullae; systemic signs and symptoms such as vertigo, DIC, or coagulopathy; abnormal laboratory values
IV	Lethal envenomation with widespread edema, shock, seizures, coma, renal failure, bleeding, DIC, paralysis

DIC, disseminated intravascular coagulation.

L-Amino acid oxidase

edema, pulmonary edema and hemorrhage, significant interstitial fluid sequestration, and hypotension. Other venom proteins appear to induce a neuromuscular blockade or coagulopathy. Procoagulant venom factors seem to dominate, primarily exerting their effect late in the clotting cascade by activating factor X or prothrombin or by directly converting fibrinogen to fibrin.¹⁰ Tissue destruction is aided by several different proteins. L-Amino acid oxidase causes extensive tissue destruction and splits fibrinogen, leading to platelet trapping and unstable clot formation, thus contributing to the genesis of disseminated intravascular coagulation (DIC). Phospholipase A₂ causes hydrolysis of lecithin at the C-2 position, resulting in the formation of lysolecithin. This event alters the permeability of erythrocyte membranes and muscle cell plasma membranes, leading to hemolysis and tissue edema. Hyaluronidase induces the lysis of ground substance and thereby aids in the distribution of the venom throughout body tissues.

The Elapidae snake venom also contains specific and unique neurotoxins and cardiotoxins, which have a more direct effect on the neuroactivity of the prey. Coral snake venom directly blocks action of acetylcholine receptor sites that do not appear to be responsive to neostigmine. This blockade results in ptosis, dysphagia, and slurred speech and can lead to seizures, coma, and death within 8 to 72 hours. While coral venom is extremely toxic, there has been only one confirmed death in the United States from a coral snake bite in the past 40 years, the victim delaying medical attention; alcohol was involved.^{10a}

Signs and Symptoms of Envenomation by Snakebite.

- 3 The important signs and symptoms of snakebites include both local and systemic effects. Immediate pain and progressive edema and erythema at the site of the bite are the norm. Local signs and symptoms progressing at a rate of greater than 30 cm/h, in addition to microscopic hematuria and bleeding from the puncture sites, indicate significant envenomation.¹¹ Delayed toxicity has been observed on occasion, and rarely severe toxicity has followed resolution of initial local symptoms.¹² Occasionally, a bite by a nonpoisonous garter snake (*Thamnophis* species) can be confused at an early stage with the bite of a poisonous snake of the Crotalidae family. Edema and erythema can be produced by toxic salivary secretions of a parotidlike gland (Duvernoy glands) if the skin has been broken.¹³ Systemic signs fail to develop, however, and the local signs resolve spontaneously within a few days.

Myonecrosis at or near the bite site is affected by both the direct toxic effects of the venom and the added ischemia of edema and increased compartment pressures. The development of a frank compartment syndrome after a snakebite of the extremity can occur but is unusual, occurring in only 1 of 272 Eastern diamondback and water moccasin bites in one report.¹⁴ Studies using purified venom injected into the anterolateral leg compartment of mongrel dogs determined that only intramuscular injection leads to an increase in compartmental pressure.¹⁵ Compartment syndromes are unusual because most snakebites do not penetrate through the superficial fascia; the principal cause of myonecrosis is probably direct toxicity of the venom rather than ischemia from elevated compartment pressure. Nonetheless, in one report of 36 rattlesnake bites, three definitive diagnoses of compartment syndrome were made on the basis of elevated compartment pressures.¹⁶ The indication for fasciotomy remains controversial, with some authors recommending fasciotomy in nearly all cases,¹⁷ but others believing that aggressive use of antivenin precludes the need for fasciotomy in most instances.

Shock is a common finding with significant systemic envenomation, resulting from increased microvascular permeability and the loss of plasma volume. Bradycardia and arrhythmia result from the cardiotoxins. Renal failure may occur from hypoperfusion and shock, from DIC with renal tubular necrosis, or as a direct toxic effect of the venom. Sheehan syndrome of pituitary

necrosis has been reported after a Russell viper bite, likely a result of the procoagulant activity of the viper's venom.¹⁸

The hematologic effects of venom cause both local and systemic problems. Venom appears to activate factor X as well as factors V and IX or directly converts fibrinogen to fibrin, leading to activation of the coagulation cascade and a consumptive coagulopathy.¹⁸ The prothrombin time (PT) and partial thromboplastin time (PTT) are commonly increased, which may result in persistent bleeding, ecchymosis, or petechiae at the puncture site or affected extremity. Microscopic hematuria and bleeding from any preexisting condition, such as peptic ulcer or menstrual bleeding, may aggravate the situation. Venom also causes a mild defibrinogenation state, with unstable clot formation consuming fibrinogen but sparing platelets. This state may contribute to DIC.

Venom also appears to cause myriad neurologic effects, especially the venom from the Elapidae family. The venom of coral snakes, cobras, and sea snakes contains an acetylcholinesterase receptor antagonist that causes ptosis, slurred speech, and impaired swallowing leading to hypersalivation. This venom also has central nervous system activity that results in progressive weakness, paresthesia, and eventually respiratory muscle failure and respiratory arrest. Seizures and psychotic behavior may develop that can lead to coma or death in 8 to 72 hours. The toxins responsible include neurotoxin A, which appears to act on the central nervous system, and neurotoxin B, which acts at the myoneural junction.

Clinical Evaluation of Snakebites. Victims of snakebites require the same aggressive supportive and resuscitative care as any trauma patient. Attention to airway and breathing are the first priority, followed by cardiovascular assessment and resuscitation. A detailed history is often helpful in determining the type and size of snake, the circumstances of the bite, and timing. Key points should include snake description, first-aid measures applied, known allergies and comorbidities, and history of snakebites or use of antivenin. A complete and detailed physical examination should specifically look for fang marks (usually a single pair, rarely more than one strike), distance between fang marks (indicates size of the snake), and measurement of the zone of erythema and edema initially surrounding the fang marks and subsequently over time. Signs of toxicity to be searched for include petechiae, bruises, bullae, or blisters. Measurements at the same site should be repeated every 15 minutes until edema and erythema progression has ceased. Frequent clinical examinations should focus on neurologic, hematologic, and hemodynamic profiles.

Initial laboratory testing should include electrolytes, complete blood count with platelet count, PT, PTT, fibrinogen level, blood urea nitrogen, and serum creatine plus urinalysis. Depending on the patient's age and comorbidities, an electrocardiogram and chest radiograph should be included. Type and cross-matching for blood is advised, particularly if the patient presents with a more severe grade of injury. Tetanus immunization status should be queried and brought up to date if needed. Enzyme-linked immunosorbent assays (ELISAs) have been developed to directly measure serum venom antigens in patients and to help identify the species of snake.¹⁸ ELISA is sensitive to 5 mg/L of venom and can assess serum, urine, blister fluid, or aspiration fluid. This test is helpful when attempting to determine the specific snake to direct monovalent antivenin therapy. Radioimmunoassay is extremely sensitive, with some venoms being detected to levels of 0.4 mg/L. The applicability of this assay is limited because of its expense and the fact that it may take 24 hours to produce a definitive result.¹⁹ In the United States, however, there is only one Crotalidae antivenin and only one coral snake antivenin; therefore, this more detailed identification is usually unnecessary.

Treatment of Snakebite Envenomation. First aid is simply immobilization and splinting of the injected part at the

level of the heart or at a slightly dependent position, much as a fracture of the extremity would be treated. The utility of incision and suction at the puncture site has been debated for years, and probably should not be advised. In dogs, up to half of the venom can be removed if incision and suction are begun within 3 minutes of the bite,¹⁹ and in rabbits, a suction device (the Sawyer extractor pump) has been shown to remove up to 37% of radiolabeled venom in rabbits when applied 3 minutes after envenomation³⁴; however, these results have not been verified in humans. Russell² has indicated that if immediate incision and suction is started and continued for 1 hour, at best 11% of the venom may be removed.²⁰ Most authorities do not recommend incision and suction therapy.^{1,20,20a,21}

The use of a proximal tourniquet should also be discouraged because it may lead to venous congestion and increased edema and ischemia without demonstrated benefit. Cryotherapy (ice pack) is discouraged universally because it increases tissue ischemia. The effects of cryotherapy and steroids were studied in envenomated mongrel dogs, and it was found that no added benefit could be demonstrated by using corticosteroids or cryotherapy as adjuvants to antivenin alone.²²

Tetanus prophylaxis and the prevention of secondary infections are important objectives of snakebite treatment. Species of the gram-negative bacteria *Aerobacter*, *Proteus*, and *Pseudomonas* are particularly common causes of bacterial infection, and appropriate systemic antibiotics are given routinely. Cholinergic agonists may be of benefit after an Elapidae bite because this venom has a significant effect on acetylcholine receptors. Calcium gluconate may also be of benefit after an Elapidae bite to control the onset of seizures. Some snake venoms have been shown to contain metalloproteases, and for this reason, ethylenediaminetetraacetic acid (EDTA) has been tried experimentally in animals as a chelator to inactivate these proteins. The use of this agent is to be discouraged, however, because it appears to hasten death in laboratory animals for unknown reasons.¹⁶ Systemic steroids have no effect in the initial treatment of snakebites, but they play a significant role in treatment of serum sickness that often follows antivenin therapy.²³

Antivenin is the mainstay of treatment of significant envenomation throughout the world.¹ While more than 100 antivenin* products are available worldwide, prior to 2007 there were two antivenins available in the United States for Crotalinae bites and one for Elapidae bites. In 2007, the manufacturer of Crotalinae equine polyvalent antivenin (Wyeth-Ayerst, St. David's, Pennsylvania) stopped distribution of this antivenin in the United States, although unexpired stock may still exist. The Crotalinae equine antivenin by Wyeth-Ayerst was a polyvalent, hyperimmune equine serum produced by horse envenomation with the eastern diamondback, western diamondback, tropical rattlesnake, and fer-de-lance. The high rate of hypersensitivity and serum sickness reactions was the primary reason for halting its use. Anaphylaxis is reported in 3% to 54% of patients treated with equine antivenin, but only 14% of those treated with ovine CroFab.^{5,25} The anaphylaxis is a type I immunoglobulin E-mediated reaction to the horse serum, which results in massive mast cell degranulation.

The other available antivenin for Elapidae bites is the eastern coral snake antivenin, also manufactured by Wyeth-Ayerst.

Since 2000, the sheep (ovine)-produced antivenin, polyvalent Crotalinae ovine immune Fab (CroFab, Protherics) (referred to as "FabAV"), has been the standard of treatment for most North American snakebites. FabAV contains only the

venom-binding portion of immunoglobulin G. CroFab (Crotalinae Polyvalent Immune Fab [Ovine]; Fougere, Melville, New York) is a sterile, nonpyrogenic, purified, lyophilized preparation of ovine Fab (monovalent) immunoglobulin fragments obtained from the blood of healthy sheep immunized with one of the following North American snake venoms: *Crotalus atrox* (western diamondback rattlesnake), *Crotalus adamanteus* (eastern diamondback rattlesnake), *Crotalus scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus* (cottonmouth or water moccasin). To obtain the final antivenin product, the four different monospecific antivenins are mixed. Each monospecific antivenin is prepared by fractionating the immunoglobulin from the ovine serum, digesting it with papain, and isolating the venom-specific Fab fragments on ion exchange and affinity chromatography columns.³³

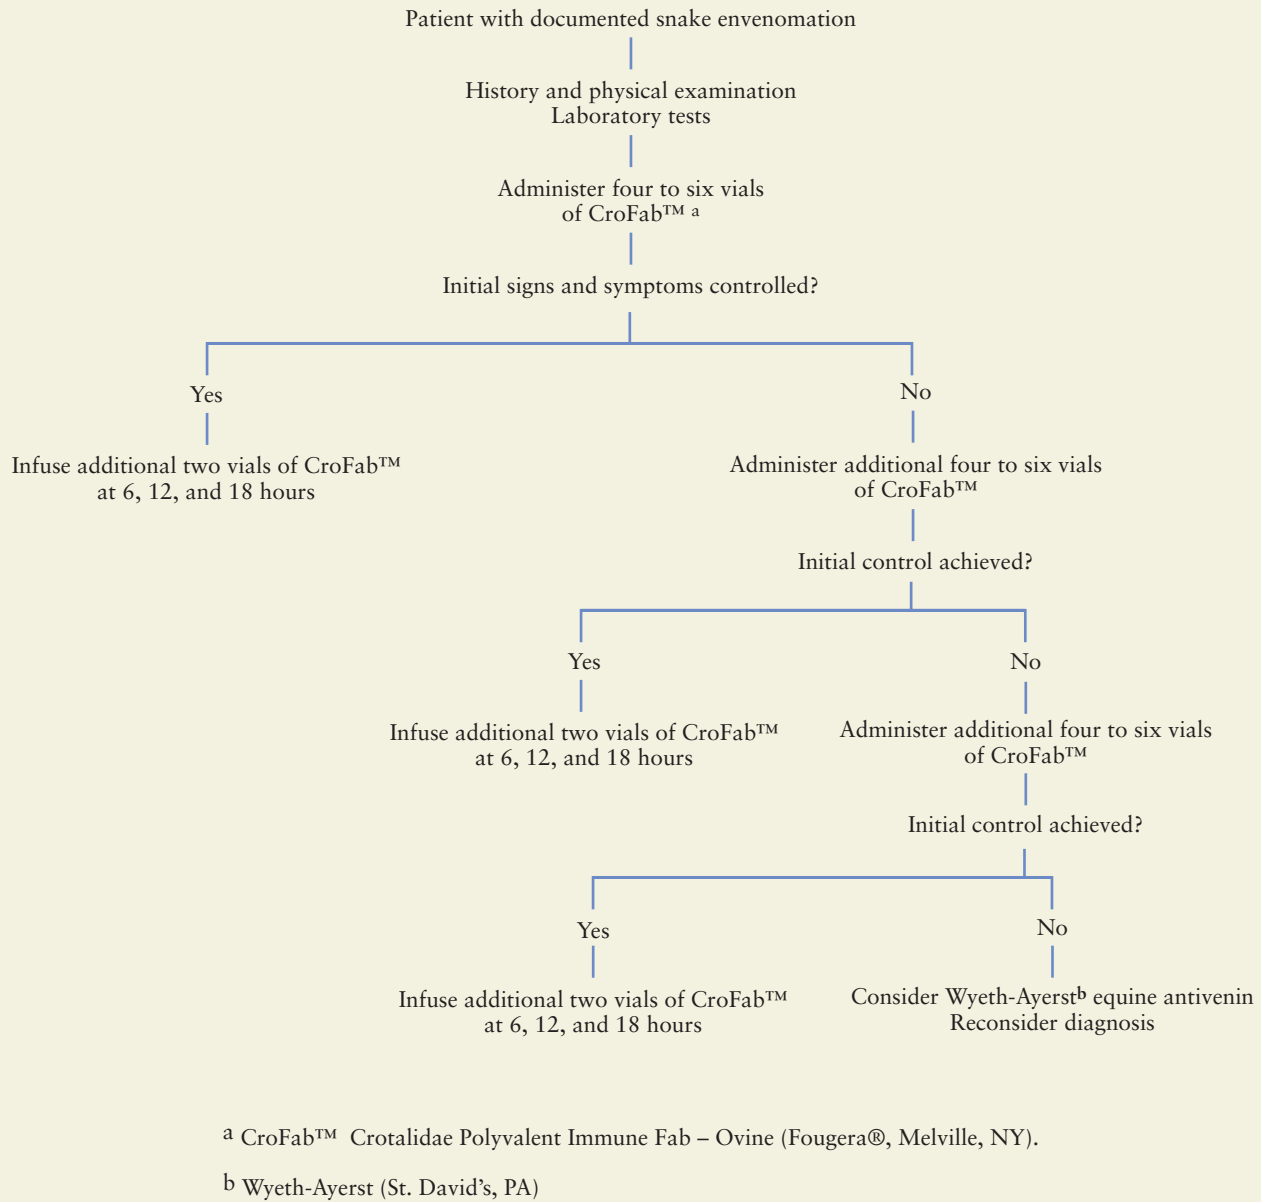

CroFab is standardized by its ability to neutralize the lethal action of each of the four venom immunogens following intravenous injection in mice. The potency of the product varies with each batch; however, a minimum number of mouse LD50 neutralizing units against each of the four venoms is included in every vial of final product. A schema for using CroFab to treat snakebites is given in Algorithm 31.1. This product is roughly five times more potent than the older equine Crotalinae polyvalent antivenin; it has rapidly replaced the equine antivenin once widely used against all North American crotalids, primarily because of fewer allergic reactions.^{5,29,30} Recurrence of the effects of venom after an initial response to antivenin has been well recognized, hence the subsequent smaller doses 6, 12, and 18 hours following an effective initial response. As the algorithm illustrates, however, the equine antivenin may still have a role in the patient who is a nonresponder to CroFab, and an equine antivenin remains the most effective antivenin for coral snake bites.

The occurrence of anaphylaxis during or after administration of any antivenin mandates immediate cessation of therapy and countermeasures, including antihistamines (oral diphenhydramine), epinephrine infusion, and/or corticosteroids. The adequacy of the airway and volume status must be ensured. The risk of continuing antivenin must be weighed against the potentially fatal consequences of severe envenomation. Concomitant administration of intravenous antihistamine and epinephrine in small, titrated microdrip doses to prevent the most severe manifestations of systemic anaphylaxis has been described in an allergic patient in whom antivenin therapy was deemed essential. This technique requires close physician observation because there are risks from both anaphylaxis and the treatment itself.

The other major complication of any antivenin therapy is serum sickness. Serum sickness occurs in approximately 50% to 75% of all patients treated with an equine-based antivenin but only 16% with the ovine source of antivenin.^{5,24} Serum sickness is a type III hypersensitivity reaction in which soluble antigen-antibody complexes are deposited diffusely in the presence of antigen access. In 26 patients who were treated with a total of 507 vials of Crotalinae antivenin, there was a 23% incidence of immediate hypersensitivity reaction and a 50% incidence of serum sickness.²⁴ Of patients who received more than eight vials of antivenin, 83% experienced serum sickness compared with 38% of patients who received fewer than eight vials. Serum sickness symptoms of urticaria, itching, nephritis, and arthralgia can occur at any time up to 3 weeks after antivenin therapy. The exact number of vials of antivenin required to induce serum sickness is unknown, but it appears that increasing amounts of antivenin lead to a higher incidence of serum sickness, with almost universal occurrence after the administration of 7 to 10 vials of antivenin. The treatment for serum sickness is systemic corticosteroids in decreasing doses over a 7- to 14-day period.

Treatment of snakebites with antivenin has changed with the more widespread use of the ovine polyvalent CroFab. As illustrated in Algorithm 31.1, patients with a suspected or

*Regarding the terminology for envenomation, the term *venom* describes the poisonous fluid produced by snakes, spiders, scorpions, etc., and the term *venin* describes any poisonous substance found in venom; *antivenin* is the term used by both *Stedman's Medical Dictionary* and *Webster's English Dictionary* to describe an antitoxin or antiserum against an animal or insect venom.

**ALGORITHM 31.1**

ALGORITHM 31.1. Treatment of snakebite envenomation with antivenin. (Adapted from Gold BS, Dart RC, Barish RA. Bites of venomous snakes. *N Engl J Med* 2002;347:347–356; and Cribari C. *Management of Poisonous Snakebites*. Chicago, IL: American College of Surgeons Committee on Trauma Poster; 2004.)

confirmed envenomation are recommended to receive an initial four to six vials of CroFab. If signs and symptoms of envenomation are controlled, additional vials are administered in a delayed fashion to prevent recurrence of symptoms. However, if the initial treatment fails to control envenomation, an additional four to six vials of CroFab are repeated twice, and then consideration should be given to using the “older” Wyeth-Ayerst polyvalent equine antivenin. The estimated initial amount of Crotalidae antivenin needed should correlate with the presenting clinical grade of envenomation. The package insert for Wyeth-Ayerst Crotalidae Antivenin Polyvalent provides detailed instructions for preparing, administering, and dosing this agent.

Although early surgical excision of the bite wound has been advocated by some, most authorities regard antivenin as the

primary therapy and reserve surgery for the occasional compartment syndrome or débridement of necrotic tissue at the site of the bite several days after envenomation. Unless deep intramuscular envenomation has occurred and antivenin therapy has been delayed, fasciotomy is rarely required. Because the musculature and deep compartments of the hand are relatively superficial, however, intramuscular penetration may occur at these sites. Myonecrosis and interstitial edema may cause enough compartmental hypertension in these sites that linear finger fasciotomy and digital release are helpful. Fasciotomy may help reduce the ischemic tissue damage caused by increased pressure but does not alleviate the myonecrosis caused by the direct toxic effect of the venom.^{31,32} Noninvasive arterial studies may help select patients who require special surgical intervention for ischemia.³³

Venomous Lizards, Lizard Bites, and Crocodile Attacks

Two species of venomous lizards exist, *Heloderma suspectum* and *Heloderma horridum*. *H. suspectum*, or the Gila monster, is found in the southwestern United States, and *H. horridum*, or the Mexican beaded lizard, is found in central and southern Mexico.³⁵ Physicians may, however, encounter a bite victim anywhere in the world because these colorful animals are common in zoos and often are kept illegally as pets. Nonetheless, human envenomation is very unusual, with only a few case reports of Gila monster or Mexican beaded lizard envenomation, and occurs most often from captive animals.^{35,36}

Gila monsters grow up to 55 cm in length. They characteristically have slow, lingering movements, but they also have surprisingly quick reflexes and incredibly powerful jaws. Although usually docile, the medical literature reports suggest they can strike without warning or provocation. The mechanism of envenomation is fairly inefficient. The lizard has eight pairs of inferior labial glands located on either side of the lower jaw that secrete venom into the floor of the mouth. By capillary action alone, the venom travels out of the glands and into grooves of the posteriorly curved lower canines (teeth 4 through 7, counting from the central incisor). Only approximately 60% of bites have significant envenomation because prolonged chewing is required to disperse the venom adequately into the prey. Dislodging the animal from its prey, however, may be difficult because of its extremely powerful jaws. It may be necessary to cut the powerful masseter muscles to pry open the lizard's mouth. More ill-advised techniques of grabbing the tail or igniting the lizard (flame under the lower jaw) have also been attempted. The teeth of the Gila monster are poorly anchored and periodically shed. Wounds must be thoroughly explored for the teeth because soft tissue radiographs often fail to demonstrate these foreign bodies.³⁵

In general, Gila monster bites have local effects, with direct tissue destruction and capillary membrane injury by serotonin, amine oxidases, phospholipase A, hyaluronidase, and a variety of proteases. The exact composition of Gila monster venom has not been elucidated, although the U.S. Food and Drug administration in April 2005 approved the use of a new injectable drug for the treatment of type 2 diabetes derived from Gila monster venom. Amylin Pharmaceuticals, Inc. (San Diego, California) and Eli Lilly and Company (Indianapolis, Indiana) codeveloped Byetta, a 39-amino-acid, glucagonlike peptide-1 agonist derived from the venom of *H. suspectum* and the first approved drug of a class called *incretin mimetics*, hormones secreted by the gut that help spur insulin production. The peptide appears to spur insulin production only when blood glucose levels are high, decreasing the risk of hypoglycemia. Clinical trials have been initiated comparing this drug alone and in combination with metformin and sulfonylureas.³⁷

The most common clinical symptom of a Gila monster bite is pain, usually subsiding in 8 to 10 hours, although it may persist for several days. Generalized weakness, dizziness, perspiration, and anxiety are other common symptoms. Hypotension is a common clinical finding with envenomation, usually responding to fluid resuscitation alone. There has been one reported case of significant systemic hypotension and myocardial infarction in a 23-year-old man after a Gila monster bite.³⁸ Other common signs include erythema, edema, and even lymphangitis, probably from pathogens injected at the time of the bite because injection of sterile venom produces none of these clinical signs. Rather severe nausea and vomiting can also be seen. Laboratory abnormalities are rare. The treatment of Gila monster bites is largely local wound care and systemic support of the patient (fluids, pain relief, antibiotics, antiemetics). No antivenin is available. Tetanus immunization should be current. A period of observation after the bite to assess the potential for systemic toxicity is warranted.

Crocodile and alligator attacks on humans are not uncommon in certain parts of the world. Saltwater crocodiles (*Crocodylus porosus*) are formidable predators in northern Australia. They are the largest of 23 species of crocodilians and are indigenous to southeast Asia and northern Australia. They are significantly larger than North American alligators or Nile crocodiles, averaging 5 meters in length versus 3 to 3.5 meters. The largest recorded was 8.5 meters in length and weighed 2 tons.^{39a} Injuries sustained are primarily from the forceful jaws, conical teeth, and heavy skull, resulting in mangled extremities infected with gram-negative water-borne organisms. While humans are usually not strong enough to force open a crocodile jaw, the strategy of applying forceful pressure to the reptile's eyes may be more than folklore. Of course, shooting the beast or beating it with a large stick may also provoke a release of the victim. Prevention is the best form of treatment.

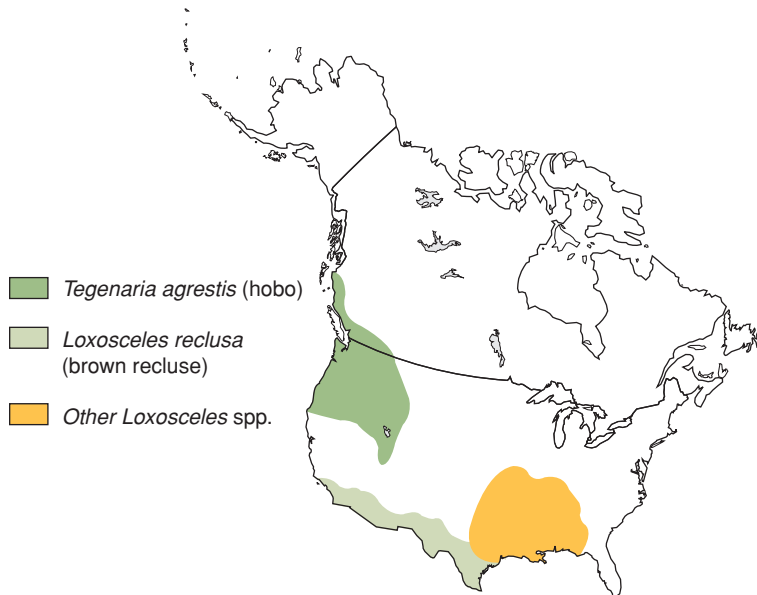

Venomous Spiders and Spider Bites

- 4 More than six genera of spiders in the United States can inflict painful bites and necrotic ulceration, but most widely known and ones of medical significance are *Loxosceles reclusa* (brown recluse spider), *Tegenaria agrestis* (hobo spider), and *Latrodectus mactans* (black widow spider).⁶⁰ In the United States, the brown recluse spider is native to the central South, whereas other *Loxosceles* species exist in the southwestern border state regions³⁹ (Fig. 31.2). Sighting of the brown recluse outside its native region is rare, is usually attributed to shipping of the spider in boxes of possessions or commerce, and is a single specimen only, not the typical large populations of spiders that exist when the habitat is conducive to their survival. The hobo spider is indigenous to the Northwest, whereas the black widow spider resides throughout the United States, except for Alaska.⁴⁰

The brown recluse and hobo spiders can cause a painful, slow-healing, necrotic ulceration, but not all painful ulcerations should be attributed to spider bites. The complaint of "spider bite" commonly accompanies a cutaneous abscess. When a spider has not been positively identified as the offending agent, consideration should be given to other possible causes of necrotic ulceration.^{39,41,42} Lyme disease (*Borrelia burgdorferi*) in particular can present with the classic "bull's eye" patterning characteristic of the brown recluse bite.⁴³ Lyme disease is caused by an *Ixodes* tick-borne spirochete and is most common in the Northeast, Middle Atlantic area, and upper Midwest. Lyme disease is important to distinguish because early treatment with antibiotics (doxycycline) is usually curative, whereas unrecognized infections can cause late arthritic and neurologic symptoms that may not respond to antibiotics.

T. agrestis was introduced to the Pacific Northwest in the early 1900s from Europe. It was first reported from Seattle in the 1930s and had become common by the 1960s. *T. agrestis* is long legged (40 mm resting length), is hairy, and ranges in color from light tan to dark brown. The cephalothorax (10 to 12 mm) is distinguished by two stripes and "butterfly" markings on the dorsal surface and two stripes marking the ventral surface. *T. agrestis* is a poor climber and hence is usually found in low places. Sometimes referred to as an "aggressive house spider," the hobo builds a funnel-shaped web that can be found in woodpiles, crawl spaces, barns, haystacks, and objects that have not been moved in a long time. The hobo spiders are active from spring through fall, and although not overtly aggressive, the most dangerous time to encounter the hobo spider is during the fall mating season; the nests should be avoided and not probed with a finger. A bite of the hobo spider causes a necrotic wound similar to that of the brown recluse spider, along with a characteristic persistent headache.³⁹ The ulcer is slow to heal, often leaving a central crater.

FIGURE 31.2. The geographic distribution of medically relevant spiders in North America.

The brown recluse spider is so named because it lives in dark, dry places, emerging only at night. This spider does not spin a web but catches prey by pursuit. It is small (body, 0.5 to 1 cm wide; leg span, 3 to 4 cm) and recognizable by the characteristic violin-shaped mark on the cephalothorax. When viewed under a microscope, it has three pairs of eyes rather than the two pairs most spiders have. Like most biting spiders, the brown recluse spider bites humans only when trapped or crushed against the skin. Brown recluse spider bites cause a complex and chronic soft tissue ulcer. Clinical signs begin first with an erythematous papule (2 to 8 hours), followed by white vasoconstriction (8 to 72 hours), ecchymosis (24 to 72 hours), and a hemorrhagic vesicle (48 to 96 hours).^{39,41} Two to 7 days after the bite, an eschar develops over a characteristic crateriform ulcer, with surrounding soft tissue induration.⁴⁴ The eschar may conceal a progressive undermining necrosis that can persist for months. These wounds are most severe in the fatty parts of the body, such as the thighs and buttocks, perhaps because of the relatively poor blood supply to these tissues. There may also be a particular dermonecrotic factor in brown recluse venom. Sphingomyelinase D is present in the venom and appears to interact with the sphingomyelin of the red blood cell membrane and perhaps capillary endothelial cell membranes, causing cell destruction.⁴⁵ Histologically, the site of the bite is said to resemble a cutaneous Arthus reaction, with the mechanism involving interactions between complement neutrophils and the clotting system.⁴⁶ Investigations suggest the necrosis is completely dependent on the victim's neutrophils, yet these neutrophils are not activated by the venom. *Loxosceles* venom appears to be a novel yet potent endothelial cell agonist, stimulating the release of interleukin-8 and granulocyte-macrophage colony-stimulating factor and E-selectin expression.⁴⁷

Significant systemic symptoms after a brown recluse bite occur infrequently, in fewer than 10% of cutaneous manifestations. The clinical spectrum includes fever, chills, malaise, arthralgia, nausea and vomiting, and a scarlatiniform rash but can progress to hemolytic anemia, renal failure, and DIC in rare cases, perhaps more commonly in children than adults.⁴⁸

Treatment of brown recluse spider bites includes analgesics, wound care, antitoxin therapy, avoidance of early surgical débridement, and perhaps oral dapsone. Antibiotics are reserved for true associated cellulitis. Dapsone is thought to work as an inhibitor of polymorphonuclear leukocyte chemotaxis, but it can cause hemolysis in glucose-6-phosphate dehydrogenase-deficient patients and can produce methemoglobinemia. Some studies show dapsone effective in reducing

the size of the skin lesion and limiting the need for surgical débridement,^{49,50} whereas other studies demonstrate no benefit in animal models,⁵¹ and no prospective study in humans supports its use.⁵² The most common dose is 50 to 100 mg (0.7 mg/kg) twice daily for 3 days to 2 weeks, although it is not approved for this use by the U.S. Food and Drug Administration. One controlled trial of dapsone, electric shock therapy, or no therapy in guinea pigs injected with 30 mg of spider venom demonstrated efficacy of dapsone in reducing lesion induration and necrosis area 72 hours after envenomation.⁵³ Electric shock therapy had no benefit. Hyperbaric oxygen treatment of model envenomation in rabbits and pigs also failed to demonstrate any effect on lesion healing time or superficial appearance, although hyperbaric treatments seemed to have decreased the amount of undermining necrosis visualized histologically on day 24 after envenomation.^{54,55} A trial of hyperbaric oxygen, dapsone, and cyproheptadine in rabbits also failed to demonstrate any significant difference in lesion size, ulcer size, or histopathologic ranking up to 10 days after injection of toxin.⁵⁵ Local injections of lidocaine, phentolamine, and systemic steroids and antihistamines have been widely used in the past but have no demonstrable benefit. Systemic corticosteroids probably have a role only in the rare case of systemic loxoscelism, which has minimal skin changes but produces massive hemolysis.⁴⁴ Surgical excision of the lesion itself has no clear benefit.⁵⁶

Commercial antivenin for the brown recluse spider is not available in the United States, although a rabbit antivenin for *L. laeta* is available in South America.³⁹ Equine-derived antivenin has been shown effective in mice and rabbits, and pepsin treatment to isolate the F(ab')₂ monoclonal fragment has been attempted. However, studies to date fail to demonstrate any advantage to antivenin, with or without dapsone, particularly if there is a few-hour delay in administering the antivenin. In areas where *Loxosceles* spiders are endemic, vaccination might hold promise.⁶⁰

Few living creatures invite such poetic fascination and fear as the black widow spider. Its name, coloring, carnivore diet, and the disconcerting habit of the female eating her sexual partner invite such fascination. And although both the male and female spider possess potent venom, only the female is dangerous to humans because the male is smaller and thus its bite cannot penetrate human skin. The mature female has a black body, approximately 6 mm in diameter, with a characteristic red hourglass mark on the ventral aspect of the thorax. This mark is not always present and may consist only of two red dots. The black widow prefers a dry, protected, dimly lit area with access to flies

and other insects, such as an outdoor privy. During the period in which the female *L. mactans* is guarding an egg sac, she is particularly aggressive and will attack the male if he disturbs the web, hence earning the particularly dark and descriptive common name *black widow*.⁴⁹ The diet most commonly consists of insects of any size, but reportedly includes mice, toads, and tarantulas that wander into the dense web and succumb to the poisonous bite and organ liquefaction.

Black widow venom has a systemic neurotoxin, the primary effect of which is chest pain and abdominal pain. The abdominal pain may mimic an abdominal crisis, with marked cramping and a rigid abdomen. The neurologic signs of hyperreflexia, paresthesia, and cutaneous hyperesthesia help distinguish this from a true intra-abdominal catastrophe. Profuse sweating, hypertension, and tachycardia are also common.⁵⁷ The primary treatment is supportive care and narcotics and muscle relaxants (methocarbamol or benzodiazepine) for pain control, although antivenin therapy also provides effective pain relief in patients with severe envenomations.⁵⁸ Antivenin is a horse serum-derived immunoglobulin therapy, usually suggested for use in young patients (<6 years of age), very infirm patients, and patients with a severe reaction. The usual dose is 1 ampule in 50 mL of normal saline. Calcium gluconate, 10 mL of a 10% solution given intravenously over 15 to 20 minutes, has usually been considered the first-line treatment of severe envenomations, although one report disputes its efficacy at pain relief.⁵⁸ Most black widow spider bite symptoms resolve within 1 day, but recurrent symptoms may persist for 2 to 3 days. Antivenin has been reported to be effective up to 30 hours after a bite.⁵⁹ The reported mortality rate is 2% to 6%, usually as a result of severe acute or delayed hypersensitivity reactions with paralysis, hemolysis, renal failure, and coma.

Venomous Hymenoptera Species and Bites

The more than 100,000 species of Hymenoptera consist of the well-known families of bees, wasps, and hornets but also include the fire ants, a nonwinged Hymenoptera present in the southeastern United States.⁶¹ More envenomations and deaths (approximately 40 annually) in the United States are caused by Hymenoptera stings than by snakebites, emphasizing the fact that the venom of most Hymenoptera is as toxic as the rattlesnake's venom, the difference being the volume administered. The venom is primarily a hemolysin and neurotoxin, known for triggering anaphylactic reactions. Bee venom also contains melittin, phospholipase A₂, and hyaluronidase, which when given in adequate volume can cause endothelial disruption, cell breakdown, and tissue necrosis. It is estimated that approximately 0.4% of the human population is at risk for anaphylaxis from Hymenoptera stings.⁶² Fortunately, most sting reactions are mild, involving dermal manifestations (e.g., hives, edema) only. The clinical effects are related both to the local toxic effects and to the anaphylactic systemic effects. The local toxic effects include significant pain, swelling, and pruritus. If a significant amount of toxin is injected, the patient may experience nausea, emesis, and muscle spasms.

Most deaths from Hymenoptera stings are a result of severe anaphylactic reaction, which can occur at any age, but is relatively more common in adults. In this reaction, a preformed immunoglobulin E antibody activates mast cells, leading to degranulation with massive histamine release and prompting laryngeal and pulmonary edema, vasodilation, and vascular collapse. The treatment for Hymenoptera bites and stings is to remove the stinger, treat the local wound with ice and possibly an enzymatic meat tenderizer, and treat the anaphylactic reactions aggressively with antihistamines (diphenhydramine, 50 to 100 mg intramuscularly or intravenously) or epinephrine (1:1,000 dilution, 0.3 to 0.5 mL intramuscularly or subcutaneously). Patients also require supplemental oxygen and intravenous fluids.

After sting anaphylaxis, approximately 50% of patients remain allergic to subsequent stings, in part determined by the severity of the initial anaphylactic symptoms. Children with benign dermal reactions only are unlikely to have recurrent reactions. Patients with more severe reactions are at risk for repeat anaphylaxis. Patients with a history of insect sting anaphylaxis and positive venom skin tests should have epinephrine available and are candidates for subsequent venom immunotherapy, which provides almost 100% protection against subsequent sting reactions. Such desensitization, however, can take more than 3 years.⁶²

Africanized bees (*Apis mellifera scutellata*) are a more aggressive subspecies than the native European bees of North and South America. Initially imported from Africa to Brazil in 1956 in the hope that they would hybridize with the better honey-producing European bee, some escaped and began interbreeding with domestic bees, proliferated, and migrated through Central America and the Yucatan peninsula of Mexico, first detected near Hidalgo, Texas, in 1993 and reportedly advancing at a rate of 100 miles per year.^{63,64} Currently located primarily in the arid southwestern United States, these bees now pose a significant threat because massive envenomations (more than 50 bites) have occurred, resulting in nausea, vomiting, shock, hemolysis, rhabdomyolysis, and DIC; coma and renal failure may follow. Rarely, in patients initially complaining only of pain after multiple bee stings, a delayed (6 to 48 hours) toxic reaction has been reported. Some poison centers now recommend a 24-hour hospitalization for pediatric patients, older patients, and patients with underlying medical problems after an envenomation of 50 or more stings because such patients have an increased risk of delayed severe systemic reaction.⁶⁵ Laboratory studies on patients sustaining massive envenomations should be performed on presentation and 6 hours later to rule out hemolysis, thrombocytopenia, liver function abnormalities, and rhabdomyolysis.

Two species of imported fire ants now infest large areas of the Gulf Coast states.⁶⁶ The most aggressive species, *Solenopsis invicta*, has adapted well to environmental conditions in the southern United States, where it has become a considerable agricultural pest and a significant public health problem. Sting reactions typically include a dermal wheal-and-flare reaction followed by sterile pustules at sting sites. Occasionally, large local dermal reactions and pyoderma, or even life-threatening anaphylaxis, can occur. Caplan et al.⁶⁷ have shown that residents of Augusta, Georgia, an endemic area, had a 17% incidence of fire ant–specific immunoglobulin E compared with a 7.5% incidence of peanut-specific immunoglobulin E, posing a significant risk of potential fatal anaphylaxis.⁶⁷ Four venom allergens have been isolated and characterized. Clinical studies under way are designed to compare the safety and efficacy of fire ant venom with whole-body extract for diagnosis and treatment of fire ant allergy.⁶⁶ Additionally, biologic control of fire ants by the release of multiple species of decapitating flies has shown promise in keeping the fire ant population under control.⁶⁸

Scorpions and Scorpion Stings

More than 650 types of scorpions can be found worldwide. In the United States, most scorpion stings are not lethal and the sting results primarily in local effects. In parts of Brazil, Mexico, North Africa, India, and Israel, however, the scorpion sting may be lethal. The venom toxicity depends greatly on the species, season, and age of the scorpion. In a fatal response, the venom induces a sympathetic storm, resulting in hypertension, tachycardia, and high-output cardiac failure.⁶⁹ Serum biochemistry reveals increased potassium and glucose, decreased sodium, and markedly elevated catecholamine levels. The treatment is specific antivenin therapy and systemic support directed at controlling hypertension and acute pulmonary edema. The outcome in the United States is usually

excellent, with complete resolution of local effects; however, in some parts of Brazil, the mortality rates for a scorpion sting have been reported to be as high as 12% in adults and 60% in children.⁷⁰ In India, of 34 children admitted to a hospital after scorpion sting, 14 had hypertension, nine had acute pulmonary edema, five had myocardial failure, and four died.⁶⁹ In one report from Israel, respiratory distress was the main feature in 17 of 54 children with scorpion stings, but only three required mechanical ventilation; two patients died, but both failed to receive antivenin.⁷¹ However, another report from Israel evaluated the treatment of 104 children with scorpion envenomation, noting that since 1989 they had discontinued using antivenin, with similar, if not better, results in the no-antivenin group.⁷² The antivenin in this report, however, is prepared from donkeys treated with the venom of the yellow scorpion (*Leiurus quinquestriatus*), which is not the same as that of the North American bark scorpion (*Centruroides exilicauda*) antivenin.

Clinically significant scorpion envenomation by *Centruroides sculpturatus* produces a dramatic neuromotor syndrome and respiratory insufficiency that often necessitate intensive supportive care, particularly in children. In a randomized, double-blind study, the efficacy of scorpion-specific F(ab')₂ antivenom was compared with placebo in 15 children ages 6 months to 18 years of age who were admitted to a pediatric intensive care unit in Tucson, Arizona, with clinically significant signs of scorpion envenomation.^{71a} The clinical syndrome resolved more rapidly among recipients of the antivenom than among recipients of placebo, with a resolution of symptoms in all eight antivenom recipients versus one of seven placebo recipients within 4 hours after treatment ($p = 0.001$). Plasma venom concentrations were undetectable in all eight antivenom recipients but in only one placebo recipient 1 hour after treatment ($p = 0.001$). As of this writing, this antivenom is commercially available in Mexico, but only available in the United States through an investigational new drug application.

ENVIRONMENTAL INJURIES

Hypothermia

- 5** Because humans are homeotherms, we attempt to maintain a constant body temperature despite changes in environmental temperature. Normal body temperature depends on the site of measurement and is 37°C sublingually, 38°C in the rectum, 32°C at the skin, and 38.5°C deep in the liver. Even minor deviation from normal leads to important symptoms and disability.⁷³ Humans have a remarkable capacity to dissipate heat by evaporating body water; however, our tropical evolutionary heritage has provided us with far less ability to cope with cold conditions. As a result, hypothermia can occur in a variety of clinical settings and from a number of causes (Table 31.4).

To allow for the normal circadian temperature variation of 0.5°C to 1°C, hypothermia is considered to be present in humans if the core temperature drops below 35°C (95°F). Hypothermia is usually classified by temperature zones as mild (32°C to 35°C), moderate (28°C to 32°C), or severe (<28°C).⁷³ Primary accidental hypothermia is defined as a decrease in core temperature that occurs as a result of overwhelming environmental cold stress. It most often occurs as a result of recreational misadventures that lead to cold-water immersion or prolonged environmental exposure. Secondary accidental hypothermia occurs in patients with abnormal heat production or thermoregulation, who become cold despite only mild cold stress. The most significant risk factors are advanced age, mental impairment, and substance abuse, in particular, of alcohol, although hypothyroidism, hypoadrenalism, trauma, and hypoglycemia are other risk factors.^{74,75} Chronic hypother-

TABLE 31.4

CLINICAL DEFINITIONS OF HYPOTHERMIA AND EXAMPLES OF SETTINGS IN WHICH THEY OCCUR

■ TYPE	■ SETTINGS
Accidental	Recreational environmental exposure, cold-water immersion
Therapeutic	Treatment of Reye syndrome, cardiopulmonary bypass, organ preservation
Drug induced	Alcohol, anesthetics, barbiturates, phenothiazines, morphine, other drugs
Central nervous system dysfunction	Transection of spinal cord, hypopituitarism, cerebrovascular accidents
Hypothalamic dysfunction	Wernicke encephalopathy, anorexia nervosa, head trauma, pinealoma, other tumors
Metabolic	Hypoglycemia, hypothyroidism, hypoadrenalism, malnutrition
Dermal dysfunction	Burns, erythrodermas
Traumatic	Occurs after any major injury

Adapted from Jurkovich GJ. Hypothermia in the trauma patient. *Adv Trauma* 1989;4:111-140.

mia develops in patients with impaired heat generation (i.e., the elderly and infirm) who live in unheated apartments, are under continual cold stress, and after a time are found always to have a low temperature as if they have autoregulated to a new set temperature. A multicenter review of 428 cases of accidental hypothermia reported an overall mortality rate of 17%,⁷⁶ although other reports document mortality rates as high as 80%, primarily a result of infection and underlying illness.

From 1979 to 2002, a total of 16,555 deaths in the United States, an average of 689 per year (range 417 to 1,021), were attributed to exposure to excessive natural cold (Fig. 31.3).⁷⁵ In 2002, a total of 646 hypothermia-related deaths were reported, with an annual death rate of 0.2 per 100,000 population. Most reported hypothermia-related deaths (66%)

FIGURE 31.3. Number of hypothermia-related deaths by year in the United States, 1979–2002. (After Hypothermia-related deaths—United States, 2003–2004. *MMWR Morb Mortal Wkly Rep* 2005;54: 173–175.)

FIGURE 31.4. Number and rate (per 100,000 population) of hypothermia-related deaths, by age group and gender, in the United States, 1979–2002. (After Hypothermia-related deaths United States, 2003–2004. *MMWR Morb Mortal Wkly Rep* 2005;54:173–175.)

occurred in males (Fig. 31.4), but the overall death rate (0.5 per 100,000 population) was the same for both males and females. Hypothermia-related deaths are commonly reported by states with characteristically milder climates that experience rapid temperature changes (e.g., North Carolina [0.4] and South Carolina [0.4]) and by western states that have high elevations and experience considerable changes from daytime to nighttime temperatures (e.g., Arizona [0.3]). States with the greatest overall death rates caused by hypothermia are Alaska, New Mexico, North Dakota, and Montana.

The physiologic response to hypothermia is one of transitional changes, with few exact temperature-dependent responses (Fig. 31.5). Broadly speaking, the transition from a “safe zone” of hypothermia (in which physiologic adaptations to heat loss are working) to a “danger zone” of hypothermia (in which shivering is abolished, metabolism decreases, and heat loss is passively accepted) occurs between 33°C and 30°C.

The initial effects of hypothermia mimic intense sympathetic stimulation, with tremulousness, profound vasoconstriction, and tremendous increases in metabolic rate, oxygen consumption, and minute ventilation.⁷⁷

The initial cardiovascular response includes tachycardia, followed by progressive bradycardia, which starts at approximately 34°C and results in a 50% heart rate decrease at 28°C.

FIGURE 31.5. Zones of hypothermia and corresponding physiologic responses. Wide biologic variability accounts for physiologic changes rarely occurring at the exact temperatures noted. (After Jurkovich GJ. Hypothermia in the trauma patient. *Adv Trauma* 1989; 4:111–140.)

Cardiac output initially increases with the tachycardia, then progressively decreases, with a concomitant fall in blood pressure. The cardiac conduction system is particularly sensitive to hypothermia: the PR interval, then the QRS complex, and finally the QT interval become progressively prolonged.⁷⁸ As temperature falls below 30°C, atrial fibrillation, bradycardia, and ventricular dysrhythmia become common, with asystole occurring at temperatures below 25°C.⁷⁹ Because palpating pulses or measuring blood pressure in cold, stiff, hypothermic patients is difficult, the presence of an organized cardiac electrical rhythm should be taken as a sign of life that contraindicates cardiopulmonary resuscitation chest compressions, despite the absence of a palpable pulse. Such a rhythm may provide diminished but sufficient circulation in patients with severely reduced metabolism, and it is likely that vigorous chest compressions will convert this perfusing rhythm to fibrillation. Rewarming with close monitoring of rhythm, pulse, and blood pressure is indicated. If cardiac arrest occurs, extracorporeal cardiopulmonary bypass for perfusion and rewarming is indicated.^{80–82} One report noted excellent long-term functional outcomes in 15 of 32 young patients successfully rewarmed in this manner.⁸¹ All patients were intubated and ventilated and had received ongoing cardiac massage during transportation, and all 15 survivors had documented circulatory arrest (ventricular fibrillation or asystole) and fixed, dilated pupils. The mean interval from discovery of the patient to rewarming with cardiopulmonary bypass was 141 ± 50 minutes; the mean temperature was $21.8^\circ\text{C} \pm 2.5^\circ\text{C}$. A report from Finland documents a 61% (14 of 23) survival to hospital discharge for adults undergoing cardiopulmonary bypass after a mean of 70 minutes of cardiopulmonary resuscitation following hypothermic arrest primarily from cold-water immersion or exposure.⁸²

Respiratory drive is increased during the early stages of hypothermia, but below 33°C progressive respiratory depression occurs, resulting in a decrease in minute ventilation. This decrease is not usually a significant problem until temperatures below 29°C are reached. Occasionally, hypothermia results in the production of a large amount of mucus (cold bronchorrhea).⁸³ This development predisposes to atelectasis and aspiration because ciliary action and the cough reflex are also depressed. Noncardiogenic pulmonary edema is also occasionally reported, especially in elderly patients and especially after prolonged periods of hypothermia.⁸⁴

The effect of core hypothermia on arterial blood gas interpretation warrants a comment. Arterial blood gas samples are typically warmed to 37°C before measurement. A nomogram of Severinghaus mathematical corrections is then used to estimate the blood gas values at the patient's actual body temperature. With each 1°C temperature reduction, the partial pressure of carbon dioxide (PCO_2) decreases by 4.4% and the partial pressure of oxygen (PO_2) decreases by 7.2%. Thus, a blood gas measured at 37°C with a PCO_2 of 40 mm Hg and a PO_2 of 70 mm Hg in a 32°C patient is reported as having a PCO_2 of 32 mm Hg and a PO_2 of 48 mm Hg after temperature correction.

The decrease in partial pressure is related to the increased solubility of gases in cold fluids and is not a result of a change in carbon dioxide content, oxygen content, or serum bicarbonate level. Clinicians often assume that the normal PCP_2 and PO_2 at 37°C are the values that should be attained at all temperatures. However, if normothermic endpoints for PCO_2 are attained in a hypothermic patient, they would have increased total body CO_2 stores, which would manifest by a rising PCO_2 and a falling pH during rewarming. Likewise, attempts at increasing a PO_2 that reflects normal oxygen content at a lower temperature are also inappropriate. A far simpler strategy is to assess the blood gases at 37°C without temperature correction. Values that are normal and acceptable when reported at 37°C correspond to normal values and contents when “corrected” for hypothermic temperatures.

Temperature correction of blood gases for pH management is also unnecessary. A pH of 7.40 at 37°C would be temperature

corrected to 7.47 in a 32°C patient. At 37°C, the acid-base balance of water is neutral (pH is equal to pOH) when the pH is 6.8, and the body functions optimally when its pH is offset 0.6 pH units above the neutral point of water and has a relatively alkaline pH of 7.40. The pH of water rises with cooling, causing the pH of blood to rise by 0.015 pH units/°C, without a change in bicarbonate content.^{85–87} Treating a patient with a temperature of 30°C with a pH of 7.40 instead of 7.47 fails to maintain the normal pH offset above the neutral point of water (relative alkalinity) and results in an acidotic cellular and chemical environment that has a multiplicity of effects on enzyme systems. Because blood with a pH of 7.40 assessed at 37°C is reported as having a pH of 7.47 when temperature is corrected to 32°C, the simplest strategy when confronted with a patient with a temperature of 32°C is to assess the blood gas at 37°C only and to use the 37°C uncorrected pH value for management.^{87,88}

The neurologic response to hypothermia is heralded by progressive loss of lucidity and deep tendon reflexes and, eventually, by flaccid muscular tone. Patients are often amnesic below 32°C, and between 31°C and 27°C they usually lose consciousness. Pupillary dilatation and loss of cerebral autoregulation occur at temperatures below 26°C, and electroencephalography becomes silent at 19°C to 20°C.⁸⁹ These findings, combined with an unobtainable pulse and apparent rigor mortis, may cause the patient to appear dead. It is important to remember that patients have been revived from core temperatures as low as 14°C,⁹⁰ hence the saying “No one is dead until they are warm and dead.” An exception to this admonition probably includes the patient who has sustained an anoxic event while still normothermic and has a serum potassium level greater than 10 mmol/L.^{82,91} The reduction in blood pressure and cardiac output decreases glomerular filtration rate, but urinary output is maintained because of an impairment in renal tubular Na^+ reabsorption (cold diuresis).^{92,93} Vasoconstriction also results in an initial increase in central blood volume that prompts a diuresis. Ileus, bowel wall edema, depressed hepatic drug detoxification, punctate gastric erosions (Wischnewsky ulcers), hyperamylasemia, and, rarely, hemorrhagic pancreatitis are hallmarks of the intestinal response to hypothermia. Hypothermia inhibits insulin release and insulin uptake at receptor sites, making hyperglycemia a relatively common finding, especially at temperatures below 30°C.⁹⁴ Exogenous insulin administration is unwarranted because it may result in rebound hypoglycemia during rewarming. Serum electrolyte changes are unpredictable, but serum potassium is often slightly increased in hypothermic patients because of renal tubular dysfunction, acidosis, sodium wasting, and the breakdown of liver glycogen.⁹⁵ Hypothermia also appears to affect endothelial cell adhesion molecule function and neutrophil recruitment and bactericidal activity, which may partially explain increased infectious complications in hypothermic patients.⁹⁶ Only a 1.9°C core hypothermia triples the incidence of surgical wound infection following colon resection and increases the duration of hospitalization by 20%.⁹⁷

Body temperature has a significant effect on oxygen uptake. Oxygen consumption (VO_2) increases dramatically with any fall in body temperature. When involuntary muscle contractions in the form of shivering occur, oxygen consumption increases by as much as threefold to fivefold.^{98,99} However, this process is inefficient because shivering produces heat near the surface of the body, causing most of the heat to be lost to the environment, with less than 45% being retained by the patient. In addition, shivering cannot be maintained due to the enormous energy requirements.

The thermoregulatory drive is such a powerful one that it takes precedence over many other homeostatic functions. The resultant increase in oxygen utilization may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress. One study noted a 35% increase in oxygen consumption and a 65% increase in CO_2 production in postoperative patients

after resolution of anesthesia, when the thermostatic drive reappeared.¹⁰⁰ In another study, a core temperature decrease of as little as 0.3°C in postoperative patients was associated with a 7% increase in VO_2 , and temperature reductions between 0.3°C and 1.2°C were associated with a 92% increase in VO_2 , with proportional increases in minute ventilation.¹⁰¹ Further details of the specific organ system responses to hypothermia are beyond the scope of this chapter, but the interested reader is referred to several excellent in-depth monographs.^{73,101–103}

Hypothermia in Trauma Patients. Mild hypothermia is very common after traumatic injury. When ambient temperature falls below the thermoneutral temperature (i.e., the temperature at which no thermogenesis or heat dissipation is necessary), which is 28°C (82.5°F) for humans, an increase in heat production is required to maintain a normal body temperature. Combustion is the only source of endogenous heat production, and this process requires an increase in energy and oxygen utilization. After shock or injury, however, oxygen supplies are often limited and further heat loss occurs owing to cold emergency department and operating room environments, cold fluid resuscitation, and open thoracic and abdominal cavities. This is further aggravated by anesthetic and neuromuscular blocking agents that prevent the heat-producing shivering response. Thus, the occurrence of hypothermia in surgical or critically injured patients is most often a form of secondary unintentional hypothermia.

One study found that 57% of trauma patients admitted to a level 1 trauma center were hypothermic at some time and that temperature loss was most significant in the emergency department.¹⁰⁴ Another study reported that the average initial temperature for 94 intubated major trauma victims was 35°C, with no seasonal variation.¹⁰⁵ Of patients in this study, 66% were hypothermic on admission: 43% were mildly hypothermic (34°C to 36°C) and 23% had temperatures below 34°C. Likewise, Jurkovich et al.¹⁰⁶ reported that 42% of 71 adult trauma victims with an Injury Severity Score (ISS) of 25 or higher had core temperatures below 34°C and in 13% the core temperature fell below 32°C. Importantly, there were no survivors when core body temperature was below 32°C. Both mortality rate and the incidence of hypothermia increase with higher ISS, massive fluid resuscitation, and the presence of shock, but even controlling for these variables still demonstrates that the mortality rate of the hypothermic trauma patient is greater than that of the warm trauma patient.^{106,107}

8 Although the mortality rate for moderate (28°C to 32°C) degrees of primary incidental hypothermia is approximately 20%,⁷⁶ moderate levels of hypothermia in trauma and critically ill patients are associated with a much higher mortality rate. Rutherford et al.¹⁰⁸ reported that 9.4% of surgical intensive care unit patients had a core body temperature less than 35°C; the mortality rate of the hypothermic trauma patients was 53%. In fact, compared with other patient populations, the mortality rate associated with hypothermia in the trauma victim is so high that the definition of mild, moderate, and severe hypothermia in the trauma patient warrants special reclassification (Table 31.5).⁷³

Hypothermia appears to occur primarily in victims of relatively severe trauma. Little and Stoner,¹⁰⁹ reporting on a heterogeneous group of 82 trauma patients, observed that hypothermia occurred only in those patients with an ISS greater than 12. Skin temperature fell from 32.0°C to 31.7°C, whereas core temperature fell from 37.3°C to 36.5°C. Hypothermia did not occur in less severely injured patients, and shivering, which should be expected, was noted in only one of the hypothermic patients. Mild degrees of injury have, in fact, been associated with small elevations in core body temperature, particularly when the shivering response mechanism has not been abated.^{73,110}

The detrimental effect of hypothermia in the human trauma victim is contrasted by a large body of experimental evidence in animals, suggesting that hypothermia has a protective role in shock. This extensive body of literature is reviewed elsewhere,⁷³ but in general, animals subjected to combined hypothermia and shock (hemorrhage, burn, blunt trauma) usually survive longer than similarly injured but actively warmed animals. Blalock and Mason¹¹¹ were among the first in modern times to recognize the ability of hypothermia to prolong survival times after shock, but they emphasized that the overall survival rate was unchanged, an observation reaffirmed in 2003.¹¹² However, other investigators have shown increases in both survival times and survival rates in a number of animal models of induced hypothermia after hemorrhagic shock.^{113,114} The protective effects of hypothermia in preventing ischemia-reperfusion injury have been described in a number of models, including muscle, intestine, and rabbit ear.^{115–118}

Hypothermia has also been suggested to protect the traumatically injured brain. The use of therapeutic hypothermia in a patient with traumatic brain injury was first reported in 1943¹¹⁹ and sporadically over the ensuing two decades.¹²⁰ More recently, a randomized, multicenter, controlled trial of core body hypothermia in trauma patients with severe closed head injury (Glasgow Coma Scale scores of 3 to 7) was conducted.¹²¹ Select trauma patients with severe head injury were intentionally cooled within 6 hours of injury to 32°C to 33°C for 48 hours after injury and then rewarmed. The outcome was poor (defined as severe disability, a vegetative state, or death) in 57% of the patients in both groups. Mortality was 28% in the hypothermia group and 27% in the normothermia group ($p = 0.79$). The patients in the hypothermia group had more hospital days with complications than the patients in the normothermia group. The authors concluded that treatment with hypothermia is not effective in improving outcomes in patients with severe brain injury. Other authors have also reported higher rates of pneumonia and diabetes insipidus in a small study of induced hypothermia in severely head-injured patients (Glasgow Coma Scale scores of 3 to 7) with no effect on neurologic outcome.¹²² Evidence further supporting the harmful effect of hypothermia in the trauma patient is provided by a prospective randomized trial of rapid rewarming versus conventional rewarming of 57 multiple-trauma patients.¹²³ In this study, trauma patients who were rapidly rewarmed with continuous arteriovenous rewarming from less than 34.5°C to greater than 36°C required less resuscitation fluid volume and had a lower early mortality rate than those rewarmed more slowly. Failure to rewarm in either group was uniformly fatal. The survival rate at 3 days after injury was 82% in the rapid rewarm group versus 62% in conventionally managed patients. Approximately 50% of the patients in both groups had a severe head injury, defined as a head Abbreviated Injury Severity score of 3 or greater. In this well-controlled study, maintenance of hypothermia not only failed to confer an advantage but also was detrimental to early survival.

The role of hypothermia in the injured patient remains unresolved. It is apparent that the physiologic consequence of severe trauma is a drop in core body temperature. It remains unclear, however, whether this response is a protective response

TABLE 31.5 CLASSIFICATION

ZONES OF SEVERITY FOR HYPOTHERMIA

■ ZONE	■ TEMPERATURE
Mild hypothermia	36°C–34°C (<96.8°F–93.2°F)
Moderate hypothermia	34°C–32°C (<93.2°F–89.6°F)
Severe hypothermia	<32°C (<89.6°F)

to shock or the result of diminished heat production caused by failing metabolism. The frequent presence of lactic acid accumulation in cold, seriously injured patients supports the latter hypothesis. Clinical studies indicate that even mild hypothermia in the trauma patient is predictive of a poor outcome. Hypothermia does diminish metabolic demands and oxygen consumption in anesthetized patients, but the price appears to be malfunction of enzymes and physiologic systems necessary to recover from injury.

The systems most affected by hypothermia in victims of injury are those involved in clotting. Reports of coagulation abnormalities in patients with apparently normal clotting factor levels surfaced shortly after the introduction of hypothermic cardioplegia for cardiac surgery.^{124,125} Although hemodilution with volume expanders deficient in clotting factors and platelets is the usual cause of nonsurgical bleeding, cold platelets are known to undergo morphologic changes that affect adherence, including loss of shape, cytoplasmic swelling, and dissolution of cytoplasmic microtubules necessary for normal motility.¹²⁶ Platelet activation is also associated with activation of cell membrane phospholipases that hydrolyze phospholipids to arachidonic acid, a precursor to prostaglandin endoperoxides and thromboxane A₂, a potent vasoconstrictor necessary for normal platelet aggregation.¹²⁷ Valeri et al.¹²⁸ induced systemic hypothermia to 32°C in baboons, but kept one forearm warm using heating lamps and a warming blanket. Simultaneous bleeding time measurements in the warm and cold arm were 2.4 and 5.8 minutes, respectively. This effect, which was reversible with rewarming, appeared to be mediated by cold-induced slowing of the enzymatic reaction rates. A recent report suggests that bleeding observed at mildly reduced temperatures (33°C to 37°C) results primarily from a platelet adhesion defect and not reduced enzyme activity or platelet activation; however, at temperatures below 33°C, both reduced platelet function and enzyme activity likely contribute to the coagulopathy,¹²⁹ perhaps helping to explain why 32°C is such a critical temperature for survival in the coagulopathic injured patient.

As with blood gases, clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. Thus, tests of coagulation reflect clotting factor deficiencies but are corrected for any potential effect of hypothermia on clotting factor function. A detailed study of the kinetic effects of hypothermia on clotting factor function has been undertaken by Reed et al.,¹³⁰ who performed clotting tests (PT, PTT, and thrombin time) on reference human plasma-containing normal clotting factor levels at temperatures ranging from 25°C to 37°C. The results showed a significant slowing of all coagulation tests at temperatures below 35°C that was proportional to the degree of hypothermia. The prolongation of clot formation occurred at clinically relevant levels of hypothermia and was equivalent to that seen in normothermic patients with significant clotting factor depletion. For example, assays conducted at 35°C, 33°C, and 31°C prolonged the PTT to the same extent as would occur in a euthermic patient with reductions in factor IX levels to 66%, 32%, and 7% of normal, respectively.

Clotting factor supplementation is not the answer to a hypothermia-induced coagulopathy; rewarming is. However, in many seriously injured patients, clotting factor depletion exists in conjunction with hypothermia. A potentiating effect of hypothermia on coagulation dysfunction occurs in plasma of patients with deficient clotting factor levels, although there does not appear to be synergy between the two conditions.¹³¹ Hypothermic, coagulopathic trauma patients still benefit from coagulation profile testing. If prolongation of PT and PTT is evident in plasma warmed to 37°C, clotting factor replacement is indicated. If PT and PTT are near normal, rewarming alone reverses the clinically relevant coagulopathy.

9 Treatment. Rewarming techniques are usually classified as passive external rewarming, active external rewarming, or active core rewarming.¹³² Passive external rewarming simply implies allowing spontaneous rewarming to occur with the patient removed from a hypothermic environment and is usually used only for the mildly hypothermic patient. Active external rewarming techniques include surrounding the patient with warm blankets or heating pads, infrared heating lights, or immersion in warm water. Active core rewarming includes heated intravenous fluids, as well as heated peritoneal or thoracic lavage; heated gastric, bladder, or colonic lavage; heated and water-saturated inhaled air; and extracorporeal circulatory rewarming. Blood rewarming is currently limited to a maximum temperature of 42°C by the American Association of Blood Banks, but rewarming to 49°C with inline microwave blood rewarmers has been reported as safe, as has intravenous fluid rewarming to 65°C.^{133,134}

The advantages and disadvantages of each technique are regularly debated, particularly regarding the role of external versus core rewarming. It is clear, however, that the rate of heat transfer to the hypothermic patient is greatest using active core rewarming, particularly extracorporeal circulation rewarming. This may be a critical factor in surgical patients for whom rapid restoration of clotting and cardiac function is necessary.

The technique of rewarming the hypothermic victim by extracorporeal circulation has been described by numerous authors, based primarily on small personal experiences.^{81,82} This technique has appeal in cases of primary accidental hypothermia, in which maintenance of circulation, correction of hypoxia, and replenishment of intravascular volume may play a role as large as correcting the temperature change itself. The need for systemic anticoagulation has, however, generally limited the usefulness of full cardiopulmonary bypass rewarming in the trauma patient.

A simplified technique of extracorporeal active core rewarming is continuous arteriovenous rewarming (CAVR).¹³⁵ This technique makes use of the patient's own blood pressure to drive an extracorporeal circuit through an efficient but small countercurrent heat-exchange device (Sims Level 1, Rockland, Massachusetts). Systemic anticoagulation is not necessary if the tubing is heparin bonded and trauma patients are relatively anticoagulated. The relative ease of use made this device widely applicable in rewarming severely hypothermic patients with an intact circulation and, in a prospective randomized trial of rewarming trauma patients, demonstrated its efficacy by improved survival.¹²³ Unfortunately, as of 2007, the single manufacturing company for the tubing needed for CAVR halted production.

Direct intracirculation rewarming can be accomplished with commercially available devices that employ an intra-vena caval countercurrent heat exchange device (InnerCool Therapies, San Diego, California; Alsius Corporation, Irvine, California). While initially developed to cool patients for neurosurgical procedures and for induced resuscitative hypothermia following cardiac arrest, rewarming can be accomplished by simply changing the temperature of the closed-loop circulating fluid. Requirements are the commercial bedside console and specialized endovascular temperature control catheter, inserted via the femoral vein to the vena cava via an 11- to 12-French introducer. Preliminary data on rewarming cold patients suggest that rewarming can occur rapidly, up to 3°C per hour.^{123a}

The use of body cavity lavage with warm solutions is a simple, less invasive method of accomplishing active core rewarming; however, rewarming rates with body cavity lavage vary greatly based on initial core temperature, dialysate temperature, infusion rate, and dwell time. Several studies support the notion that active core rewarming by peritoneal lavage is preferable to active external rewarming.¹³⁶ Moss⁷⁴ examined three techniques of rewarming hypothermic and cardiac-arrested dogs, concluding that both peritoneal lavage (55°C dialysate) and partial extracorporeal circulation were faster than active external

rewarming with a heating blanket.⁷⁴ A frequently stated disadvantage of external rewarming is that the peripheral tissues are rewarmed in advance of the still cool “core,” resulting in peripheral vasodilation. In the presence of inadequate volume resuscitation, this rewarming method may result in vascular collapse (“rewarming shock”) and a subsequent fall in central temperature (“afterdrop”) as the cold peripheral blood returns to the core. Volume contraction caused by vasoconstriction, cold diuresis, and cellular swelling coupled with inadequate fluid resuscitation may be a more appropriate explanation for circulatory collapse during rewarming.

The thermodynamic principles of heat transfer to the hypothermic patient are reviewed in greater detail elsewhere, but a sense of rewarming rates and quantity of heat transferred by various techniques is instructional.^{132,137} Ventilating a patient with a core temperature of 32°C with water-saturated air at 41°C results in a maximum heat transfer rate of 9 kcal/h. For comparison, basal metabolic heat generation produces approximately 70 kcal/h, and shivering produces up to 250 kcal/h. Given the specific heat of the body (0.083 kcal/kg per °C), 58 kcal is required to raise the temperature of a 70-kg patient by 1°C. Thus, more than 6 hours would be required to warm a 32°C patient using 41°C humidified inspired air.

Heat transfer rates using body cavity lavage can be similarly calculated based on the specific heat of water (1 kcal/kg per °C). If 1 L of 44°C water infused into a body cavity dwells long enough to exit at 40°C, 4 kcal of heat will have been transferred to the patient. Thus, over 14 L of fluid is needed to increase core temperature by 1°C. However, warming becomes less efficient as the patient rewarms because a longer dwell time is required to reduce the temperature of the infusate to 40°C.

Warming by cardiopulmonary bypass or continuous arteriovenous rewarming is the most efficient method of core heating. With flow rates of 15 to 30 L/h, it is possible to deliver 120 to 240 kcal/h if the reinfused blood is heated to 40°C, a rate of heat transfer over 10 times that of the other methods. In each case, the urgency with which rewarming must be accomplished depends on how adversely the hypothermia is affecting the patient. With the exception of extracorporeal circulatory methods, most rewarming techniques serve primarily to prevent further loss of endogenously generated heat and are ineffective in circumstances during which rapid rewarming is indicated. Early and direct attention to the mechanisms of heat loss is necessary to optimize prevention of heat loss and the metabolic and hemorrhagic complications associated with hypothermia in surgical patients.

Cold Injury and Frostbite

Cold injuries limited to digits, extremities, or exposed surfaces are the result of either direct tissue freezing (frostbite) or more chronic exposure to an environment just above freezing (chilblain [pernio], trench foot). Cold injury has been a major cause of morbidity during war experiences. It resulted in more than 7 million lost soldier fighting days by Allied forces in World War II and was reportedly the most common major injury sustained by British soldiers in the Falklands expedition.¹³⁸

The terms *chilblain* and *pernio* describe a form of local cold injury characterized by pruritic, red-purple papules, macules, plaques, or nodules on the skin. The lesions are often associated with edema or blistering and are caused by a chronic vasculitis of the dermis¹³⁹; this entity does not appear to be related to hereditary protein C or S deficiency.¹⁴⁰ This pathologic process is provoked by repeated exposure to cold, but not freezing, temperatures. This injury typically occurs on the face, the anterior surface of the tibia, or the dorsum of the hands and feet, areas poorly protected or chronically exposed to the environment. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of sheltering the patient, ele-

vating the affected part on sheepskin, and allowing gradual rewarming at room temperature. Rubbing and massage are contraindicated because they can cause further damage and secondary infection.

Trench foot or cold immersion foot (or hand) describes a nonfreezing injury of the hands or feet, typically in sailors, fishermen, or soldiers, that is caused by chronic exposure to wet conditions and temperatures just above freezing.¹⁴¹ It appears to involve an alternating arterial vasospasm and vasodilation, with the affected tissue first cold and anesthetic and then hyperemic after 24 to 48 hours of exposure. With the hyperemia comes an intense, painful burning and dysesthesia, and tissue damage is characterized by edema, blistering, redness, ecchymosis, and ulceration. Complications of local infection or cellulitis, lymphangitis, and gangrene may occur. A posthyperemic phase occurs 2 to 6 weeks later and is characterized by tissue cyanosis with increased sensitivity to cold. Treatment is best started during or before the reactive hyperemia state and consists of immediate removal of the extremity from the cold, wet environment with exposure of the feet (or hands) to warm, dry air. Elevation to minimize edema, protection of pressure spots, and local and systemic measures to combat infection are indicated. Massage, soaking of the feet, or rapid rewarming is not indicated. Demyelination of nerves, muscle atrophy, fallen arches, and osteoporosis may all present long-term complications, and a tendency toward marked vasospasm during subsequent exposure to cold develops in some patients.¹⁴²

Frostnip is the mildest form of cold injury. It is characterized by initial pain and pallor, with subsequent numbness of the affected body part. Skiers and other winter outdoor enthusiasts are most likely to experience this cold injury to the nose, ears, or tips of digits. The injury is reversible and warming of the cold tissue results in return of sensation and function with no tissue loss.

Frostbite is a more severe and common form of cold injury. Frostbite damage is caused by direct ice crystal formation at the cellular level with cellular dehydration and microvascular occlusion. Frostbite is traditionally classified into four grades of injury severity (Table 31.6).

The affected body part nearly always initially appears hard, cold, white, and anesthetic, regardless of the depth of injury. Because the appearance of the lesion changes frequently during the course of treatment and because the initial treatment regimen is applicable for all degrees of insult,¹⁴³ some authorities suggest discarding this classification as a prognostic impossibility and simply classifying frostbite as either superficial or deep.¹⁴⁴

Weather conditions, altitude, degree of protective clothing, duration of exposure, and degree of tissue wetness are all contributing external factors to the development of frostbite injury. Because sensory nerve activity is abolished at 7°C to 9°C, the

TABLE 31.6 CLASSIFICATION

CLASSIFICATION OF FROSTBITE

■ DEGREE	■ DESCRIPTION OF FROSTBITE
First	Tissue freezing with hyperemia and edema but without blistering
Second	Tissue freezing with hyperemia, edema, and characteristic large, clear blisters
Third	Tissue freezing with death of subcutaneous tissues and skin, resulting in hemorrhagic vesicles that are in general smaller than second-degree blisters
Fourth	Tissue necrosis, gangrene, and eventual full-thickness tissue loss

disappearance of pain is an early warning sign of cold injury. Acclimation to cold may be protective, whereas a previous history of frostbite probably predisposes to another cold tissue injury. Smoking and a history of arterial disease also are contributing factors. In urban environments, more than 50% of frostbite injuries are alcohol related and a significant portion of these patients (16%) have an underlying psychiatric illness.¹⁴⁵

10 Evidence suggests that frostbite injury has two components—the initial freeze injury and a reperfusion injury that occurs during rewarming. The initial response to tissue cooling is vasoconstriction and arteriovenous shunting, intermittently relieved (every 5 to 7 minutes) by vasodilation, the so-called hunting response.¹⁴⁶ With prolonged exposure, this response fails, and the temperature of the freezing tissue approximates ambient temperature until -2°C . At this point, extracellular ice crystals form, and as these crystals enlarge the osmotic pressure of the interstitium increases, resulting in movement of intracellular water into the interstitium. Cells begin to shrink and become hyperosmolar, disrupting cellular enzyme function. If freezing is rapid ($>10^{\circ}\text{C}/\text{min}$), intracellular ice crystal formation occurs, resulting in immediate cell death.¹³⁸ Intravascularly, endothelial cell disruption and red cell sludging result in cessation of circulation.

During rewarming, red cell, platelet, and leukocyte aggregation is known to occur and results in patchy thrombosis of the microcirculation. These accumulated blood elements are thought to release, among other products, the toxic oxygen free radicals and the arachidonic acid metabolites $\text{PGF}_{2\alpha}$ and thromboxane A_2 , which further aggravate vasoconstriction and platelet and leukocyte aggregation.^{147,148} However, the exact mechanism of tissue destruction and death after freeze injury remains poorly defined. Animal studies suggest that vascular injury in the form of endothelial cell damage and subsequent interstitial edema, but not vessel thrombosis, predominate as initial events in rewarming injury.^{149,150} A substantial component of severe cold injury may be neutrophil mediated, as suggested by the observation that a monoclonal antibody to neutrophil–endothelial and neutrophil–neutrophil adherence can markedly ameliorate the pathologic process of a severe cold injury.¹⁵¹ In this rabbit model, animals treated with anti-CD11/CD18 adhesion molecule after cold injury (30 minutes at -15°C) but before rewarming (39°C water bath) had significantly less tissue loss and edema. The implication of these observations is that much of the injury of severe frostbite occurs during rewarming or reperfusion, although recent evidence of the efficacy of intra-arterial thrombolytic therapy suggests that endovascular clotting does occur and can be reversed.^{151a}

Treatment

Prehospital or field care of the victim of cold injury should focus on removing the patient from the hostile environment and protecting the injured body part from further damage. Rubbing or exercising the affected tissue does not augment blood flow and risks further cold injury or mechanical trauma. Because repeated bouts of freezing and thawing worsen the injury, it is preferable for the patient with frostbite of the hands or feet immediately to seek definitive shelter and care rather than rewarm the tissue in the field and risk refreezing. Although the initial symptoms may be mild and overlooked by the patient, severe pain, burning, edema, and even necrosis and gangrene may appear with rewarming. With severe injury the range of motion progressively decreases and edema becomes prominent. The injury may progress to numbness and, eventually, to loss of all sensation in the affected tissue.

The emergency room treatment of a frostbite victim should first focus on the basic ABCs (airway, breathing, and circulation) of trauma resuscitation and then systemic hypothermia

should be identified and corrected. Most patients are dehydrated, and resuscitation with warm fluids is an important part of early management. Fractures are often accompanied by frostbite in mountaineers, and although manipulation may be required to treat vascular compromise, open reduction is hazardous, and application of traction should be delayed until after postthawing edema has been assessed.

Rapid rewarming is the goal. Gradual, spontaneous rewarming is inadequate, particularly for deeper injuries, and rubbing the injured part in ice or snow often delays warming and results in marked tissue loss.¹⁵² Rapid rewarming should be achieved by immersing the tissue in a large water bath of 40°C to 42°C (104°F to 108°F). The water should feel warm, but not hot, to the normal hand. The bath should be large enough to prevent rapid loss of heat, and the water temperature should be maintained. Dry heat is not advocated because it is difficult to regulate, and the result of using excessive heat is often disastrous. The rewarming process should take approximately 30 to 45 minutes for digits, with the affected area appearing flushed when rewarming is complete and good circulation has been reestablished. Narcotics are required because the rewarming process can be quite painful.

The skin should be gently but meticulously cleansed and air dried and the affected area elevated to minimize edema. A tetanus toxoid booster should be administered as indicated by immunization history. Sterile cotton is placed between toes or fingers to prevent skin maceration and extreme care taken to prevent infection and avoid even the slightest abrasion. The affected tissue should be protected by a tent or cradle, and pressure spots must be prevented. In one review, infection developed in 13% of urban frostbite victims, but one half of these infections were present at time of admission.¹⁴⁵ Most clinicians reserve antibiotics for identified infections.¹⁵³

After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. All patients should be hospitalized and affected tissue gently cleansed once or twice a day in warm (38°C) whirlpool baths, with some clinicians adding an antiseptic such as chlorhexidine or an iodophor to the bath. Based on the findings of arachidonic acid metabolites in the blisters of frostbite victims, some authors advocate the use of topical aloe vera (thromboxane inhibitor) and systemic ibuprofen or aspirin. Heggors et al.¹⁵⁴ report on a nonrandomized trial in which 56 patients treated with these agents, plus prophylactic penicillin, had less tissue loss, a lower amputation rate, and a shorter hospital stay than 98 patients treated with warm saline, silver sulfadiazine, or Sulfamylon dressings (Bertek Pharmaceuticals, Research Triangle Park, North Carolina).¹⁵⁴ Another report on frostbite treatment in rabbits demonstrated improved tissue viability when systemic pentoxifylline and topical aloe vera cream were used.¹⁵⁵ Uninfected blebs should be left intact because they provide a sterile biologic dressing for 7 to 10 days and protect underlying epithelialization. After resolution of edema, digits should be exercised during the whirlpool bath and physical therapy begun. Tobacco, nicotine, and other vasoconstrictive agents must be withheld. Weight bearing is prohibited until complete resolution of edema.

Numerous adjuvants have been suggested and tried in an effort to restore blood supply to frostbitten areas. The intense vasoconstrictive effect of cold injury has focused attention on increased sympathetic tone. Sympathetic blockade and even surgical sympathectomy continues to be advocated by some authors based on the theory that it releases the vasospasm that precipitates thrombosis in the affected tissue.^{156,157} This method of treatment has produced inconsistent results and is difficult to evaluate clinically, with no prospective randomized trials available. Although sympathectomy appears to mollify the pain, hyperhidrosis, and vasospasm of cold injuries, it may increase vascular shunting and adversely affect healing. In one series, a more proximal demarcation of injury in sympathectomized

FIGURE 31.6. Digital angiography of a 19-year-old woman who sustained bilateral lower extremity frostbite following vehicle breakdown. **A:** The image demonstrates poor distal perfusion to the left toes. **B:** Following administration of tissue plasminogen activator via bilateral femoral catheters, angiography demonstrates return of perfusion. All 10 of her toes were saved. (Reproduced with permission from Bruen KJ, Ballard JR, Morris SE, et al. Reduction of the incidence of amputation in frostbite injury with thrombolytic therapy. *Arch Surg* 2007;142:546–553.)

limbs was noted than in nonsympathectomized ones, despite apparently equal bilateral injury.¹⁵²

Experience with intra-arterial vasodilating drugs such as reserpine and tolazoline has also been unrewarding. Bouwman et al.¹⁵⁷ demonstrated in a controlled clinical study that immediate (mean 3 hours) ipsilateral intra-arterial reserpine infusion coupled with early (mean 3 days) ipsilateral operative sympathectomy failed to alter the natural history of acute frostbite injury compared with the contralateral limb. Heparin, thrombolytic agents, and hyperbaric oxygen have also failed to demonstrate any substantial treatment benefit, whereas low-molecular-weight dextran alleviated postthawing circulatory obstruction as late as 2 hours after thawing and markedly reduced tissue loss in rabbit feet.¹⁵⁸

The most recent adjunct to the management of frostbite is the intra-arterial infusion of tissue plasminogen activator (tPA). In a nonrandomized study of a small number ($n = 7$) of

patients who received intra-arterial tPA, the burn team at the University of Utah demonstrated that tPA infusion improved tissue perfusion and reduced amputations (10% vs. 41%) when administered within 24 hours of injury (six of the seven), as compared with 25 patients managed in a more traditional fashion.^{151a} Candidates for this therapy should have minimal risk of bleeding from other injuries; have the tPA administered (intra-arterially or intravenously) within 24 hours of frostbite, with no episodes of rewarming or refreezing between injury and treatment; and have clear evidence of full-thickness tissue involvement, as well as abnormal perfusion on either angiogram or pyrophosphate scanning (Fig. 31.6; Table 31.7).

The difficulty in determining the depth of tissue destruction in cold injury has led to a conservative approach to the care of frostbite injuries.^{153,159,160} As a general rule, amputation and surgical débridement are delayed for 2 to 3 months unless infection with sepsis intervenes, hence the adage: “frostbit in

January, amputate in June.” The natural history of a full-thickness frostbite injury is the gradual demarcation of the injured area with dry gangrene or mummification clearly delineating nonviable tissue. Often the permanent tissue loss is much less than originally suspected. In an Alaskan series, only 10.5% of patients required amputation, usually involving only phalanges or portions of phalanges.¹⁴¹ The need for emergency surgery is unusual, but vigilance should be maintained during the rewarming phase for the development of a compartment syndrome requiring fasciotomy. Open amputations are indicated in patients with persistent infection and sepsis that is refractory to débridement and antibiotics. Mills¹⁶¹ convincingly demonstrated that of all the factors in the treatment of frostbite that may influence outcome, premature surgical intervention by any means, in any amount, was by far the greatest contributor to poor results.

The use of technetium-99m methylene diphosphonate bone scanning has shown some promise in the early detection of eventual bone and soft tissue viability,¹⁶² as has the use of magnetic resonance imaging.¹⁶³ Technetium-99m “triple-phase” scanning (at 1 minute, 2 hours, and 7 hours) performed beginning 48 hours after admission has been used to assess early tissue perfusion and viability, in an attempt to define the extent of fatally damaged tissues and to allow for early débridement and wound closure.^{164,165} The utility of this diagnostic modality continues to evolve, however, with one recent study suggesting that the moderate to severe frostbite lesion identified by technetium-99m scans can be “hibernating” (viable) tissue, which can show improvement up to 6 months following injury.^{153,166}

Frostbitten tissues seldom recover completely. Some degree of cold insensitivity invariably remains. Hyperhidrosis (in up to 72% of patients), neuropathy, decreased nail and hair growth, and a persistent Raynaud phenomenon in the affected part are frequent sequelae to cold injury.¹⁶⁷ The affected tissue remains at risk for reinjury and should be carefully protected during any cold exposure. As mentioned previously, chilblain (or chronic pernio) is a specific form of a dermopathy secondary to cold-induced skin vasculitis. Treatment with antiadrenergic agents (prazosin hydrochloride, 1 to 2 mg/d) or calcium channel blockers (nifedipine, 30 to 60 mg/d) and careful protection from further exposure are often helpful.^{139,167} However, few therapies afford significant relief to the chronic symptoms after tissue freeze injury, although β - and α -adrenergic blocking agents, calcium channel blockers, topical and systemic steroids, and a host of home remedies have been tried with occasional individual success.

CHAPTER 32 ■ TERRORISM

ERIC R. FRYKBERG

KEY POINTS

- 1 Terrorism is random and ruthless violence against people—usually innocent civilians—and property to intimidate societies and governments for political or ideologic purposes. Terrorism has increased greatly and is the most common cause of mass casualties today. In the United States, complacency and apathy of health care providers are the greatest impediments to effective response to terrorism.
- 2 The major goals of terrorism are maximal casualties and lethality using, most frequently “weapons of mass destruction” of biologic, nuclear or radiologic, incendiary, chemical, and explosive (BNICE) agents.
- 3 Biologic weapons use microorganisms or their toxins to inflict disease. Useful because of easy deployment over wide areas, delay in onset, variability in recognition for containment, and proven effectiveness in nature (e.g., influenza epidemics), biologic weapons have been used in war since at least the Roman Empire.
- 4 Major biologic agents include anthrax (*Bacillus anthracis*), botulinum toxin (*Clostridium botulinum*), bubonic plague, tularemia, small pox, and viral hemorrhagic fever, caused by four viral groups. However, their development is dangerous, expensive, and difficult, explaining their rare use.
- 5 Chemical agents are aerosolized or gaseous, ingested as contaminated food, or absorbed by direct contact and have been used frequently during wars in the 20th century. Response requires recognition, treatment (including decontamination and protection of caregivers), and specific antidotes.
- 6 Dispersal of radioactive agents has severe theoretical risk but is primarily a psychological and panic effect. Penetration by ionizing radiation causes severe damage but is limited in range (square of the distance), and containment is relatively easy and nontransmittable. Care is supportive, treating dermal burns and gastrointestinal and hematopoietic damage.
- 7 Terrorist attacks are, by far, implemented most commonly using conventional weapons and confirm the need of a system to treat the casualties of bombings. The magnitude of energy achieved, the ease of technology required, and cost effectiveness support an ongoing increase in risk of mass casualties.
- 8 Explosion injuries are caused by the primary blast wave–induced disruption of organs with air–liquid interfaces (lung, bowels, eyes, and ears); secondary blast injury from flying objects, particularly shrapnel placed in bombs and suicide bomber body parts; tertiary blast injury from displacement of the victim’s body; and quaternary blast injury from indirect causes such as building collapse.
- 9 Response to mass casualty events requires triage of victims to effectively utilize resources, including the paradigm shift from greatest good for the individual to greatest good for the greatest number, with need for preemptive planning, coordination, and practice of an Incident Command System to respond optimally.

THE CHALLENGE

- 1 Terrorism is defined as the unlawful exercise of random and ruthless violence against people, usually innocent civilians including women and children, and property to intimidate governments or societies for political or ideologic purposes.¹ Over the past few decades, terrorist attacks on civilian populations worldwide have ranked among the most common and most prominent causes of mass casualty disasters. These attacks have increasingly confronted health care providers with the unique demands of mass casualty management and have demonstrated the importance of developing a basic knowledge and skill set for disaster planning and management within the medical community.

Among the greatest impediments to a successful response to terrorist-related disasters are the complacency and apathy that pervade the mindset of most health care providers in the United States because of the low probability of these events and the belief that this country is well protected from such attacks. Disaster and mass casualty management has never been included in medical school or residency training. Even though most terrorist attacks involve bodily injury, surgeons in particular have largely abrogated their natural leadership role in disaster planning and management to other nonsurgical specialists and even to nonmedical organizations, agencies, and personnel.² The inaccuracy of these perceptions has been

repeatedly demonstrated by the suboptimal medical response to such prominent disasters as the 1993 World Trade Center bombing in New York City; the 1995 bombing of the Alfred P. Murrah Federal Building in Oklahoma City; the Centennial Olympics bombing in Atlanta, Georgia, in 1996; and the jet-liner attacks on and collapse of the World Trade Center twin towers on September 11, 2001, among many others.^{3–6}

- 2 The two major goals of most terrorist attacks are maximal casualty generation and maximal lethality.⁷ These goals are best achieved by the “weapons of mass destruction” of biologic, nuclear or radiologic, incendiary, chemical, and explosive (BNICE) agents. Even the mere threat of these weapons is sufficient in many settings to achieve the public chaos and societal disruption that terrorists seek. It is essential that surgeons be fully prepared to meet these threats by learning the associated history, epidemiology, pathophysiology, and injury patterns, so as to allow appropriate preparation and practice for their medical management.

BIOLOGIC WEAPONS

- 3 The term *biologic weapons* as agents of terrorism refers to the deliberate use of microorganisms, or toxins derived from them, to intentionally inflict disease and death on large populations.⁸ Biologic agents have a number of features that theoretically

make them useful weapons. The most prominent such feature is that they can easily be deployed silently and anonymously over wide areas. Their incubation period results in a delayed time interval after initial exposure before the effects, and any suspicion of a terrorist attack, become manifest. A large number of casualties may occur before the medical community is able to initiate containment measures. Also, most biologic pathogens are widely available, are readily disseminated over large geographic areas, and have a historically proved capability to cause widespread disease and death (i.e., bubonic plague and influenza epidemics). In contrast, only a relatively few pathogens are believed to be suitable for potential use in terrorist attacks, and their development into effective weapons is quite expensive and difficult, which is confirmed by the extreme rarity of their use for this purpose.⁹

There is a long history of the use of biologic pathogens as weapons of war and terrorism. The contamination of drinking water with animal carcasses or human feces dates back at least as far as the Roman Empire. In 1346, the corpses of victims of an outbreak of bubonic plague among Tartar invaders of the port city of Caffa (now Feodosiya, Ukraine) on the Black Sea were catapulted into the city, which spread the disease among the Genoese defenders. It is believed that these Genoese carried this disease back to Europe to begin the Black Death epidemic that killed one third of Europe's population. During the French and Indian War in North America, the British caused an outbreak of smallpox among Native Americans by giving them gifts of disease-ridden blankets. In recent decades, countries such as Japan, Iraq, the United States, and the Soviet Union developed large-scale weaponization of anthrax, smallpox, and botulinum toxin.⁹⁻¹²

- 4 The level of threat of any biologic agent for use as a bioterrorist weapon is dependent on four factors: (a) the public health impact, in terms of its virulence, communicability, and susceptibility in exposed populations and its lethality; (b) the ease of production, delivery, and dissemination to large populations; (c) the requirements for surveillance, diagnosis, and stockpiling of treatments and antidotes; and (d) the potential for fear, panic, and societal disruption based on public perceptions. The U.S. Centers for Disease Control and Prevention (CDC) has developed three categories of threat of bioterrorist agents (A, B, and C), with the six pathogens in category A posing the greatest risks.¹³ Frontline medical providers must be aware of the clinical manifestations and treatment of these six organisms and should have a high index of suspicion for their deliberate use to contain an attack as early as possible.

High-risk Biologic Agents

Anthrax is carried by the gram-positive rod *Bacillus anthracis* and is considered the most likely agent to be used in a bioterrorist attack. Its spores can be produced easily in large quantities with little training, they can be stored for many years without loss of potency, they are undetectable by human senses, and they are easily spread in air by such delivery mechanisms as sprayers, bombs, and missiles. Conversely, a relatively high dose of 10,000 to 50,000 spores is necessary to cause infection, and the infection cannot be transmitted from person to person.^{14,15} An accidental release of anthrax spores from a Soviet military facility in 1979 led to 66 human deaths within a 4-km radius.¹⁶ One report estimates that an aerosolized release of 100 kg of anthrax spores could result in 130,000 to 3 million deaths in the Washington, D.C. area.¹⁵ Reports conflict as to how easily or cheaply weapons-grade anthrax can be produced, because the most virulent form requires that the anthrax particles be less than 5 microns in size with minimal clumping, which is difficult and expensive to achieve.

The incubation period of anthrax is between 2 and 6 days and manifests in three clinical forms: cutaneous, gastrointestinal, and pulmonary. The cutaneous form is the most common,

representing 95% of all reported cases. It occurs naturally, from exposure to infected animals, and has a 20% case fatality rate. The gastrointestinal form results from ingestion of contaminated meat and has a higher mortality rate due to its delayed recognition. It manifests nonspecific symptoms of abdominal pain, fever, nausea, vomiting, and gastrointestinal bleeding and peritonitis. The pulmonary form is the most lethal and is believed to be the most likely form to be used in a terrorist attack from an aerosolized spread. This form is 100% fatal if untreated and 80% fatal if treated after the onset of symptoms. The antibiotics ciprofloxacin and doxycycline are the treatments of choice for both active infection and prophylaxis. Vaccination is considered to be 92% effective when given after exposure.¹⁵

Botulinum toxin is a highly lethal neurotoxin produced by the organism *Clostridium botulinum*, causing a neuromuscular blockade that leads to respiratory failure. Although most commonly contracted from ingestion of contaminated food, aerosolized forms have been developed that could be especially effective as lethal weapons through inhalation. Standard gas masks provide protection from this agent, and treatment involves supportive care with mechanical ventilation until the effects subside. Antitoxins may shorten the duration of clinical effects, and vaccines are available for high-risk individuals in research and the military.¹⁵

Bubonic plague and tularemia are bacterial diseases, and smallpox is a virulent viral pathogen; all have a high case fatality rate and an established history of causing millions of deaths. Although bubonic plague and tularemia are usually spread through the bite of infected organisms (i.e., mosquitoes, fleas) and smallpox is spread by contact with infected body fluids, all can be effectively transmitted by aerosolized airborne dissemination. Bubonic plague and tularemia are treated with streptomycin as the antibiotic of choice. Vaccination is the only effective measure against smallpox and must be administered as soon as possible after exposure to prevent or minimize its consequences.^{15,17-19}

Viral hemorrhagic fever is a clinical syndrome that manifests symptoms of fever, myalgias, headaches, and malaise in association with evidence of neurovascular collapse (shock, mucous membrane hemorrhages). Viral hemorrhagic fever is caused by the four major viral groups of filoviruses (Ebola and Marburg), arenaviruses (Lassa fever), bunyaviruses (Rift Valley fever), and flaviviruses (yellow fever and dengue). Filoviruses are considered bioterrorist threats because of their ability to infect via aerosolized dissemination, their ease of replication in culture for large-scale production, and their virulence, with mortality rates ranging up to 90%. Treatment is supportive, and contact and droplet precautions are generally adequate for infection control. Antiviral drugs have shown some promise, and a vaccine is available only for yellow fever.²⁰

CHEMICAL WEAPONS

Toxic chemicals have a proven capability to cause widespread morbidity, mortality, and societal disruption among large populations and thus pose a major threat as terrorist weapons. Their deadly effects could be imparted through inhalation of aerosolized and gaseous agents, ingestion of contaminated foods, and direct contact with the skin, mucous membranes, and eyes (Table 32.1).

- 5 Poison gases have been used extensively in warfare, especially in the 20th century. In World War I, about 4% of all casualties (about 1 million people) were caused by these agents, which included 26% of all American casualties.²¹ The worst chemical disaster in history involved the accidental release of 40 tons of methyl isocyanate gas in Bhopal, India, in 1984, resulting in 2,500 deaths and an additional 200,000 casualties.²² These devastating results demonstrate how effective these agents could be in the hands of terrorists. The bomb

TABLE 32.1

DIAGNOSIS AND TREATMENT

CHEMICAL AGENTS THAT POSE A THREAT AS TERRORIST WEAPONS

■ CATEGORY	■ AGENTS	■ TREATMENT/ANTIDOTE
Pulmonary irritants	Phosgene, chlorine, ammonia, mace	Decontamination, water cleansing, bronchodilators, mechanical ventilation
Incapacitating agents (anticholinergics)	Benzene	Intravenous hydration, physostigmine
Vesicants (blistering agents)	Mustard, lewisite, phosgene oxime	Decontamination, hypochlorite, dimercaprol
Nerve agents	Tabun, sarin, soman, VX	Atropine, 2-Pam, diazepam, airway control, decontamination
Blood agents	Cyanide	Decontamination, hyperbaric oxygen, amyl nitrite

that exploded in the World Trade Center in New York City in 1993 contained enough cyanide to contaminate the entire building, but it was destroyed by the blast.²³ In 1995, the gaseous release of the nerve agent sarin in the Tokyo subway system caused 12 deaths and 5,000 injuries, representing the first terrorist use of this agent on a civilian population.²⁴

The initial phase of response to intentional chemical attacks, as well as biologic and radiologic attacks, is known as *consequence detection*. Early detection is essential if casualties and death are to be minimized and can occur from either the discovery of the source of environmental release or exposure, or the diagnosis of the afflicted casualties. Patterns of large numbers of patients with similar symptom clusters must be recognized, which requires a knowledge of the classic symptoms of chemical poisoning, including coughing and choking from pulmonary agents such as chlorine and phosgene, dry mouth and mucous membranes, seizures, eye irritation, and the cholinergic symptoms of nerve agent poisoning described by the mnemonic DUMBBELS (diarrhea, urination, miosis, bronchospasm, bronchorrhea, emesis, lacrimation, and salivation).

The response phase that involves organization and cleanup of the disaster scene and medical and psychological treatment of the casualties is termed *consequence management*. The identified source of contamination and exposure must be neutralized to prevent further damage. Health care workers must wear personal protective equipment to prevent their exposure to hazardous materials (HAZMAT), including the prevention of inhalation of toxic fumes from off-gassing that may emanate from the tissues or clothing and belongings of afflicted victims.

6 Triage and decontamination of casualties must be established outside the hospital, and away from the disaster scene, to prevent health care providers and hospital facilities from being contaminated and rendered useless for further treatment of casualties. Decontamination should furthermore take place at a site that is uphill and upwind from the scene for this purpose. A *hot zone* must be established for contaminated casualties, to be clearly demarcated from the *warm zone*, where decontamination takes place, and the *cold zone*, where casualties are considered fully decontaminated and ready to undergo re-triage and medical treatment. All casualties must undergo decontamination as early as possible to minimize adverse effects. Simply removing their clothing and showering with soap and water removes more than 90% of all contaminating agents, a process known as *gross decontamination*. The more intensive *technical decontamination* then follows for specific forms of exposure, such as hypochlorite solutions for mustard agents, and copious eye irrigation with saline solution. Poison control centers, public health officials, pharmacologists, and toxicologists are important resources and personnel who

should be involved in the planning and management of chemical terrorist disasters.

NUCLEAR/RADIOLOGIC WEAPONS

Dispersal of radioactive substances poses a significant potential for a terrorist attack because of the theoretical damage that could be inflicted on large populations, although such a deliberate attack on civilian populations has never occurred outside of war. These agents also carry the potential of widespread psychosocial effects and panic caused by the mystique that is associated with radiation among the general population. The dangers of these agents are largely overestimated, however, and result from poor understanding of radiation biology. These misperceptions are as common among health care providers as among the lay public and represent a major barrier to effective management. In fact, major radiation exposure from a terrorist attack should be easier to manage than biologic or chemical events because of easy detection methods with Geiger counters and dose-rate meters; the large number of hospital, industrial, and government personnel who regularly deal with radiation; and the well-known clinical effects that can be monitored with simple laboratory tests.^{25,26}

Radiation is categorized as nonionizing and ionizing, and may consist of particles or waves, each of which has specific implications for injury in mass casualty scenarios. Nonionizing radiation, such as infrared and visible light, has little if any injurious effects on living organisms. Ionizing radiation represents the major radiologic threat from terrorist events, as it causes damage to living cells and tissues from its direct energy as well as from the indirect effects of the unstable and toxic hyperoxide molecules it creates. These effects are long term, as they continue far beyond the time of exposure. γ -Rays and x-rays, which are examples of wave radiation, have high tissue penetrance and cause the greatest tissue damage, especially to rapidly dividing cells (gastrointestinal tract and bone marrow). Neutrons are particles that behave much like γ - and x-rays as they also have high penetrance with severe tissue damage. α (Helium nuclei) and β (electrons) particle radiation have low tissue penetrance and damage potential and are easily shielded, but cause highly lethal damage if ingested or if they gain access through open wounds.²⁵

The major factors that determine the severity of radiation exposure are time, distance, and shielding. The absorbed radiation dose rapidly decreases with shortened duration of exposure and with the square of the distance from the source, so that quadrupling the distance reduces the dose rate to one sixteenth of the original exposure. In doses of less than 1 Gy

(1 Gy = 100 rads), the biologic effects are not clinically significant, although long-term malignant transformation is always possible. The handling of highly radioactive sources or fallout of radioactive dust from α or β particles results in local skin exposure with thermal burns that are characterized by erythema, desquamation, and blistering. Treatment of these low levels of exposure includes prophylactic antibiotics and standard burn wound care.²⁵⁻²⁷

The effects of whole-body exposure from highly penetrating wave and particle sources (γ -rays, x-rays, and neutrons) are dose and duration dependent. Nausea, vomiting, diarrhea, and pancytopenia, especially lymphocyte count depression (termed *acute radiation syndrome*), begin at doses greater than 1.0 Gy. The LD₅₀ of radiation exposure, which is the dose range that will kill 50% of the afflicted casualties, is 3.0 to 4.5 Gy. An absorbed dose of 10 Gy is considered to be the highest survivable dose if maximal medical therapy is provided. Symptoms develop in less than 5 minutes following doses greater than 10 Gy, and doses greater than 30 Gy inevitably lead to death from cardiovascular and nervous system collapse in 24 to 72 hours.²⁷ Thus, the timing of onset of gastrointestinal symptomatology and lymphocyte depression can serve as accurate and easily discerned determinants of mortality risk, which greatly aids in the triage of mass casualties from a radiologic event.

The two major forms that a nuclear or radiologic terrorist attack could take are the dispersal of radioactive materials that are commonly used in industry and medicine (i.e., cobalt-60, cesium-137, iridium-192, iodine-131), most likely using conventional explosives (*dirty bombs*), and the atmospheric release of large amounts of intense ionizing radiation through the sabotage of nuclear power plants or the detonation of nuclear bombs. Dirty bombs are easy to construct with little training. They could spread contamination over a few city blocks at most and cause bodily injuries from the blast as well as fear and panic in the population. Property damage and radiation exposure are unlikely to be extensive, and the relatively small area of contamination should be easily monitored and contained for long-term cleanup. In contrast, nuclear sabotage and explosions require significant technical expertise and money to develop and execute and are therefore considered relatively unlikely to be used by terrorists. However, they threaten substantial property destruction as well as injury and death to people over a range of hundreds of miles because of the physical effects of the blast, the thermal and blinding effects of the ensuing fireball, and the high levels of ionizing radiation thrown into the atmosphere.²⁸⁻³⁰

The appropriate medical care of casualties from a radiologic incident first requires an understanding of the distinction between radiation *exposure* and radiologic *contamination*. Exposure to ionizing radiation results in damage to body tissues, and the clinical manifestations of the victim and their timing provide a reliable guide to their absorbed dose. Exposure alone does not make a casualty “radioactive,” does not require decontamination, and offers no danger whatever to medical providers. *Contamination* refers to radioactive material that is found on the clothing or body of a victim, which can be spread to medical providers and the environment and requires decontamination to reduce such spread. Treatment of these casualties is largely supportive, involving the management of the skin, gastrointestinal, and hematopoietic signs and symptoms, after removing them from the source. Internal contamination through inhalation, ingestion, or skin or open wound absorption is treated by minimizing absorption and through the use of dilution, blockage, displacement, stimulation of renal and gastrointestinal elimination, and chelation methods. Most of these approaches are largely unproved and ineffective, including bone marrow transplantation or stem cell augmentation, or they have some beneficial effect only against specific radioisotopes. There is no “antiradiation” drug or agent. Potassium iodide does effectively block thyroid

uptake of radioactive iodine, but this isotope is found only after nuclear explosions or nuclear plant leaks. Also, potassium iodide is effective only if given within 4 hours of exposure and is of benefit only in children.^{26,28}

External contamination of clothing and exposed skin is easily managed by simply removing clothing and showering with water and detergent, which should remove more than 90% of the contamination. Technical decontamination can then follow with removal or intensive cleansing of all hair and through scrubbing of the body, guided by the use of radiation dose meters to detect residual radiation. All clothing and fluid runoff is bagged and carefully disposed of to control the spread of radioactive materials. Open contaminated wounds must be washed and débrided according to standard aseptic principles, and wound excision should be considered for contamination with long-lived radionuclides (e.g., α emitters). After whole-body exposure of greater than 1.0 Gy, open wounds should be closed as soon as possible to prevent them from becoming portals of entry for lethal internal contamination. External radiologic contamination does not constitute a medical emergency for either victims or medical providers. It is best to consider radioactive contamination as nothing more than dirt, something that is preferably cleaned off before treatment or hospitalization but that should *not* cause any delay in treatment of life-threatening injuries or the withholding of appropriate medical care for fear of exposure. Life-threatening injuries that require urgent medical management should not await extensive decontamination, although removal of clothing and a quick shower can usually be accommodated. Medical personnel and hospital facilities will not be overexposed even with the highest levels of exposure and contamination of casualties, and medical personnel should simply wear protective gowns, caps, masks, and gloves in accordance with standard universal precautions.^{25-27,29} There should be no reason for hospital-based providers to ever wear any more protective gear than this for any toxic contamination. Not only is it unwarranted for radiologic contamination, but also no chemically contaminated casualty should be allowed to enter the hospital until fully decontaminated.

The overall response to a radiologic or nuclear disaster should include proper planning and preparation, training of personnel, and on-scene triage and evacuation of casualties on the assumption of hazardous internal exposure. Triage officers must be familiar with the clinical effects and treatment of radiation injury.^{29,30} National government resources should be contacted for guidance on the recognition and management of radiation exposure.²⁶ Severely injured casualties with radiation exposure should be triaged for definitive care to different facilities from those who are not seriously injured, and all possible measures to contain further contamination should be undertaken. Medical personnel should wear standard protective gear in accordance with universal precautions and treat all emergent medical and surgical problems without consideration of the radioactive contamination and exposure. Resources and procedures for dealing with the stress and psychosocial effects that are inevitably associated with radiologic incidents, in both casualties and medical providers, should be in place.^{26,29}

EXPLOSIVE WEAPONS

- 7 Explosive attacks by terrorists have typically been characterized among conventional weapons, but the magnitude of energy that terrorist bombings have achieved over the past three decades and the thousands of resulting casualties make it clear that these agents belong as much in the category of unconventional weapons of mass destruction as those discussed previously. Furthermore, explosive devices have historically been and currently are the most common weapons of terrorism by far and therefore remain overwhelmingly the

most prominent and most likely threat for which civilian populations must be prepared in the future. This has important implications for the role of surgeons in disaster planning and management because the casualties of explosive disasters will be afflicted predominantly with traumatic injuries for which surgical expertise and support are necessary. The technology required for large-scale casualty generation and lethality with this mechanism is easily learned, and its cost effectiveness is unsurpassed by any other method.^{31,32} These factors have resulted in a dramatic worldwide increase in frequency of these incidents with each passing year (Table 32.2).⁷

Historical Perspective

An analysis of two major accidental explosions of the 20th century serves to demonstrate the devastation of civilian populations that can result from large-magnitude explosive agents and provides important lessons in the planning for and prevention of their disastrous consequences. On December 6, 1917, in Halifax harbor, Nova Scotia, the Belgian ship *Imo* collided with the French munitions ship *Mont Blanc*, causing a fire on the top deck of *Mont Blanc* from the ignition of 35 tons of benzene. Hundreds of first-responder city firefighters and civilian onlookers then flocked to the scene. After 15 minutes, the fire ignited a cargo below decks consisting of 2,300 tons of picric acid, 10 tons of gun cotton, 300 rounds of ammunition, and 200 tons of trinitrotoluene (TNT). The ensuing explosion, the largest nonnuclear manmade explosion ever to occur, was followed by a 150-foot tidal wave, which leveled more than 2.5 km² of the city, blew the ship 1 mile high and vaporized it, threw its 1,100-pound anchor 2 miles away and a cannon 3.5 miles away, shattered windows 100 km away, and was heard in Boston. The resulting smoke plume rose 4 miles into the air. This delayed explosion wiped out the hundreds of curious citizens and firefighters who initially responded to the fire. There were 2,000 deaths, 9,000 injured, and more than 20,000 left homeless in a city with a population of only 50,000, and all medical facilities were destroyed.³³

In the port of Texas City, Texas, on April 16, 1947, the freighter *Grand Camp* caught fire, again attracting the entire

city's firefighters and hundreds of onlookers. Its cargo below decks of several tons of ammonium nitrate fertilizer was ignited 20 minutes later, creating an explosion with a 2,000-foot-high smoke plume and hurling the ship's anchor 2 miles away. A second more powerful blast occurred a short time later, causing widespread fires and a 150-foot tidal wave. This disaster resulted in 600 deaths in a city of only 16,000 population, including, again, the city's entire fire department and dozens of citizens initially attracted to the fire.³⁴

These disasters demonstrate how devastating explosions can be and how effectively they can achieve the terrorist aims of casualty generation and lethality with relatively little cost or training. In Texas City, simple ammonium nitrate fertilizer caused one of the largest manmade explosions ever. It is quite likely that terrorists have studied these and similar events. With the ever-increasing use of bombings as instruments of terror in subsequent years, it is clear that lessons learned from these accidental disasters have been used. Ammonium nitrate-based fuel-air explosives have been used in several major terrorist attacks to generate explosions of great magnitude (see Table 32.2). Another effective and commonly used technique in terrorist bombings has been the "second hit," so well demonstrated in both Halifax and Texas City, in which an initial event draws in onlookers and first responders, who are then wiped out by a second deliberate event—another explosion, sniper fire, or a building collapse.^{6,32,35,36} In this way, to further expand injury, death, and panic among their target population, terrorists exploit the natural and predictable urge of people to help others. This second-hit phenomenon is best combated by restricting access to any disaster scene, especially to medical personnel who have no training to manage that scene, whose help and skills are best used in the protected and resource-rich environment of hospitals, and whose deaths will further and needlessly magnify the risk to surviving casualties. The noble but emotional, ego-driven, and misguided urge to run to a scene to "help" must be restrained by a disciplined and rational analysis of how help can best be delivered.

Terrorist bombings increased dramatically in the 20th century, with 5,075 such events documented worldwide between 1973 and 1983, causing 3,689 deaths and 7,991 injuries. There was a 10-fold increase in these incidents between 1968

and 1980 as their success became evident.³⁷ In the United States alone, 12,216 terrorist bombings occurred between 1980 and 1990, with 1,582 bombings causing 222 injuries and 27 deaths occurring in 1990 alone.³⁸ From 1988 to 1997, the number of actual and attempted terrorist bombings increased by 127% within the United States, with 17,579 incidents causing 4,063 injuries and 427 deaths.³⁹ Between 1991 and 2000, 88% of all disasters involving more than 30 casualties were due to explosions.⁴⁰ Since then, major bombings of U.S. embassies in Tanzania and Kenya in 1998 and the USS *Cole* in Yemen in 2000, the jet airliner crashes into the World Trade Center and Pentagon in 2001, the Madrid train terminal bombings in 2004, the London subway and bus bombings in 2005, and the ongoing suicide bombings in Israel and Iraq have shown that explosive weapons remain the most likely mass casualty threat that must be confronted by surgeons in coming years. Analysis of these many events and an understanding of the pathophysiology of blast provide a valuable insight into the patterns of injury around which planning and management can be formulated.

Biodynamics of Blast

Terrorist bombings typically employ high-energy detonations that generate a pressure pulse wave, called a *blast wave*, which travels through air at supersonic speeds. The edge of this radially propagating wave is known as the *blast front*. Immediately following detonation, a *peak overpressure* phase, lasting only a fraction of a second, involves the sudden rise of air pressure far above ambient levels. This instantaneous rise in pressure imparts to the blast wave the characteristic of *brisance*, or shattering ability. The peak overpressure is followed by a more gradual ebbing of pressure lasting up to 10 times longer, which ends in a negative-pressure phase into which air and debris can be sucked (Fig. 32.1). This negative-pressure phase accounts for the implosion of some surrounding structures, as well as the creation of tidal waves in coastal areas, as happened after both the Halifax and Texas City explosions. The term *blast wind* refers to these rapid back-and-forth movements of air. Underwater blasts are generally three times more powerful in blast wave propagation than those in air because of the greater density of water.^{41–43}

The four factors that determine the force of a blast and the severity of injuries it causes are the size of the explosive charge, the distance from the blast, indoor or outdoor location, and the surrounding medium of air or water. The magnitude of an

FIGURE 32.1. The Friedlander curve demonstrating the pressure characteristics of a blast wave over time.

air blast tends to dissipate rapidly according to the cube of the distance from the blast, so that moving three times the distance away reduces the energy by 27-fold. Indoor detonations cause the blast energy to be magnified rather than dissipated as the blast wave is reflected off walls, floors, and ceilings, causing greater damage than open-air blasts. This magnification of destructive force explains why terrorists seek to detonate bombs in confined spaces, such as in buses in Israel, rather than open air.^{44,45}

8 The medical management of casualties of terrorist bombings requires an understanding of the three categories of injury that result from explosions. Primary blast injury is caused by the passage of the blast wave through the body, which causes a disruptive turbulence, called *spalling*, in the tissues of organs with air-to-liquid interfaces, such as the lung, bowels, eyes, and ears. For this reason, tympanic membrane rupture is quite common among casualties of explosive events and should be viewed as a sensitive marker for more severe internal effects of primary blast injury.⁴⁶ The lung is the most common visceral organ damaged in air blasts, whereas bowel disruption is found primarily in underwater blasts. Most victims of primary blast lung injury die immediately because such injuries require that they be so close to the blast that they suffer lethal bodily harm. Only 0.6% of survivors of major terrorist bombings have been found to have blast lung injury, but more than 10% of these victims ultimately die, indicating that this injury should also be considered a marker of severity that requires urgent treatment.³⁴ Blast lung is characterized by progressive pulmonary insufficiency, with radiologic and pathologic findings typical of blunt pulmonary contusion. Death is caused by cerebral and coronary air embolism.^{41,47,48} A higher incidence of blast lung injury is found among survivors of urban bombings as compared with bombings in rural and isolated locales as a result of the rapid triage and transport of victims and abundant medical resources available in larger cities.⁴⁹

Secondary blast injury is caused by the impact on the body of flying objects and debris set in motion by the blast. Tertiary blast injury involves the displacement of the victim's body to impact other objects. Both of these forms of blast injury cause the standard forms of blunt trauma that predominate among survivors of terrorist bombings and that surgeons typically manage in routine practice.^{31,32,43,44,47,48,50} Secondary blast injury has also increasingly included penetrating trauma from destructive shrapnel placed in the bombs, as well as from body parts of suicide bombers that become embedded in the victim.^{5,51,52} An especially bizarre implication of these latter injuries to both casualties and medical care providers is that the embedded terrorist body parts have been shown to carry chronic diseases, such as hepatitis and acquired immunodeficiency syndrome (AIDS), that are transmitted to surviving casualties and serve to further magnify the level of injury and terror.⁵³

Quaternary, or miscellaneous, blast injuries are indirect consequences of explosive events, including burns, crush injuries from falling debris or structural collapse, inhalational injuries from dust and toxic chemicals, and ocular injuries. The dissemination of biologic, chemical, and radiologic agents in dirty bombs falls into this category and is also called *combined blast injury*.²

Patterns of Injury, Severity, and Mortality

Terrorist bombings result in consistent and predictable patterns of injury and mortality in all published reports.^{3,31,32,47,48,50,54} The incidence of immediate deaths and critical injuries among survivors is related to the magnitude of the explosion, whether it occurs indoors or outdoors or in urban or isolated locales, and the association with building collapse. By exploding a bomb within a large building, the probability of complete structural collapse is increased, which greatly magnifies the casualty generation and lethality beyond the blast itself.³² This

TABLE 32.3

^aIncludes only 361 casualties inside the Alfred P. Murrah Federal Building stratified by portion of building in which they were located. Adapted from data in Mallonee S, Shariat S, Stennies G, et al. Physical injuries and fatalities resulting from the Oklahoma City bombing. *JAMA* 1996;276:382–387.

is another reason why terrorists seek to place explosives in buildings. In the suicide bombing of the U.S. Marine barracks in Beirut, Lebanon, in 1983, with an ammonium nitrate fuel-air explosive imparting an estimated explosive force of 6 to 10 tons of TNT, the complete collapse of the four-story building resulted in the immediate death of 68% of all 346 casualties.⁵⁵ A terrorist bombing in Buenos Aires, Argentina, in 1994, caused the complete collapse of a seven-story building, resulting in the immediate death of 29% of all casualties but of 94% of casualties within the building.⁵⁴ In the 1995 bombing in Oklahoma City, the partial collapse of the nine-story Alfred P. Murrah Federal Building, also caused by an ammonium nitrate bomb constructed as a fuel-air explosive imparting a 2-ton TNT equivalent blast force,³ resulted in significantly greater injury and death among victims in the collapsed portion of the building (Table 32.3). This is remarkably different from the 3.3% immediate death rate among the 574 casualties of the Khobar Towers bombing in Saudi Arabia in 1996, in which there was no building collapse.⁵⁶ These observations emphasize the preventive value of both barricading major buildings to prevent vehicular access and improving structural design of buildings to withstand major blasts without collapsing.

Most survivors of terrorist bombings are not critically injured. Generally only 10% to 20% of survivors require urgent treatment for severe injuries, a pattern that is typical of most mass casualty disasters from any mechanism. The most common injuries found in immediate fatalities involve the head, chest, abdomen, blast lung, and traumatic amputation. These same severe injuries are found in only a small minority of survivors (0.5% to 2%) but contribute to a disproportionately high mortality among those survivors (10% to 50%) and therefore must be considered important markers of severity that require urgent attention. The great majority of survivors have noncritical soft tissue and skeletal injuries, for which care may be delayed for hours or days if necessary to maximize casualty flow and the immediate care of critical injuries.^{3,5,6,31,32,56,57}

TRIAGE AND HOSPITAL CASUALTY MANAGEMENT

The prioritizing of patients according to injury severity, their need for immediate care, and available resources is called *triage*. In societies and geographic areas with an abundance of medical resources, such as the United States, triage is seldom necessary or practical because all injured individuals are brought to hospitals and provided with maximal care. In true mass casualty disasters, however, such as those resulting from terrorism, triage must assume major importance on the part of medical providers because of the limited resources available to the large casualty numbers. The difficulty of triage in this setting lies in the need to rapidly identify that small minority of critically injured casualties who require and are expected to

respond to immediate care from among the large majority of casualties who have noncritical or untreatable injuries, but who tend to rapidly inundate medical facilities. Although this rationing of care, and the possibility of denying care to some victims because of limited resources, is antithetical to current medical training and moral values, it may nonetheless be essential to maximize casualty survival. Disaster triage thus requires a paradigm change in mindset and approach to medical care, which in turn mandates that medical providers be educated in these principles that are so different from the routine approach to medical care.³² The goal of management must shift from the greatest good for each individual to the greatest good for the greatest number, with the population taking priority over the individual. Triage officers not only must be experienced in the care of those injuries expected in any form of disaster (i.e., trauma in explosive events), but also must understand how to assess and treat these injuries within the unique context of mass casualties.^{58,59}

The five categories of triage that are generally accepted are immediate, delayed, minimal or walking wounded, expectant, and dead. In the first triage performed at a disaster scene, the only decision made is that of who is alive and who is dead. Living casualties are then removed from the dangers of the scene to one or more *casualty collection points*, where the only decision to be made is who needs immediate care and hospital transport and who does not.^{36,58} It is best not to evacuate casualties directly to the hospital from the scene, so as to allow a systematic reevaluation and distribution of those needing hospital care among all available facilities, to avoid overloading any one hospital. As secondary and tertiary triage is performed later in the hospital, more discrimination can be applied.

The expectant category includes those casualties with such severe and extensive injuries that more time and resources would be required than is justified by the limited resources, which can better be applied to more salvageable victims. This category best illustrates the change in mindset required in mass casualty management and why special training and experience are needed to serve in the role of triage officer. A physician may be appropriate for this role, but any health care provider could fulfill this role with the proper training. In fact, physicians may be too scarce and valuable a resource to spare for this duty. Exactly what constitutes an expectant casualty must be decided early in each disaster and cannot be predicted because the definition depends on the specific types of injuries, casualty numbers, and what resources are available.^{58–61}

Errors of Triage

The accuracy of triage could certainly affect the ultimate outcome of surviving casualties. Improper assignment to a delayed category of critically ill or injured casualties who require urgent care, termed *undertriage*, is the most important

to avoid and imparts an obvious potential for preventable death in all settings. The term *overtriage* describes the assignment of noncritical casualties to immediate care. In the routine management of trauma patients, with small numbers arriving at any given time, overtriage is an economic, logistical, and administrative burden that does not affect casualty outcome and is considered necessary to minimize undertriage.⁶²

However, the published results of 10 major mass casualty disasters from terrorist bombings that relate the overtriage rate to the mortality among critically injured survivors (Table 34.4) confirms a direct impact of overtriage on the *critical mortality rate* in this setting (Fig. 32.2).^{3,43,50,54,55,63–67} This impact occurs because the inundation of a hospital with large numbers of casualties all at once, most of whom are not critically injured, impedes the ability of medical personnel to rapidly detect that small minority who require immediate care, thus increasing the risk of preventable deaths.³² It is reasonable to postulate that this principle probably applies to all mass casualty events of any mechanism, as the essential element of this problem is the overwhelming casualty load. This emphasizes the critical importance of accurate triage discrimination in all disasters to minimize both overtriage and undertriage.⁵⁹

Hospital Care Considerations

The system of casualty flow and treatment within the hospital following a mass casualty explosive event is a major factor in

FIGURE 32.2. Relationship of overtriage to critical mortality rate in survivors of major terrorist bombings, from data in Table 34.4 ($r = 0.92$). How does casualty load affect trauma care in urban bombing incidents? A quantitative analysis. *J Trauma* 2005;58(4):686–695.)

the outcome of these casualties. The abundant published information on the hospital management of terrorist bombing casualties can be extrapolated to the expected demands from disasters of all kinds.^{31,32,36,68}

Hospitals must restrict access of casualties to all but those most seriously injured in order to conserve their scarce resources and allow them to be applied to those most in need. No casualty should be allowed into a hospital before being both decontaminated and triaged. The three hospital resources most in demand in this setting are the emergency room (ER) where casualties are first received and evaluated, the operating room (OR), and the intensive care unit (ICU). Each of these units should have a designated *controller*, who is not involved directly in medical care but is responsible for the proper admission, movement, and disposition of all casualties to optimize rapid and efficient casualty handling. Casualties should always move forward through hospital spaces, never returning or going backward, thereby minimizing traffic gridlock and confusion.^{36,40,60,61,69,70}

Developing the space to accommodate the added casualty load, or *surge capacity*, is the first thing that a hospital must accomplish following a mass casualty event, and this must be done within a matter of minutes. More important is the provision of the ability to care for the casualties brought into this space (i.e., nurses; special needs such as dialysis, pediatric, geriatric, and burn care; and surgical specialists), or *surge capability*, without which the space and beds alone are of no

benefit. The most appropriate and realistic definition of surge capacity and capability is a functional one. An evidence-based computer modeling study by Hirshberg et al., using data from urban terrorist bombings, defines surge capacity as the *arrival rate* of critically injured casualties per hour that would allow at least 90% of the optimal quality of medical care to be delivered to each casualty.⁷¹ They showed the relationship between casualty arrival rate and quality of hospital care to be best described by a sigmoid curve, and that there was a precipitous decline in the quality of medical care delivered to individual casualties at more than five critical casualties arriving per hour (Fig. 32.3). This could be improved (i.e., the curve moved to the right) by effective planning and preparation. However, the quality of medical care declines more precipitously (i.e., the curve moves to the left) with increasing levels of overtriage, defined as the arrival rate of noncritical casualties who do not require hospital care, presumably because overtriage delays the recognition and treatment of the critical casualties (Table 32.5). This further emphasizes the importance of minimizing overtriage in mass casualty events.

PLANNING AND REPORTING

Advance preparations are immensely important for the success of any disaster response because disasters are completely random, unexpected, and unpredictable. However, their magnitude requires a rapid, organized, and comprehensive response involving a number of disparate elements that do not usually work together, and a medical approach that is quite different from routine patient care.⁷⁰ Such a response cannot occur without plans in place that have been extensively rehearsed.

Disasters are rare events, requiring that planning be based on the abundant literature that documents experience from past disasters. Although every disaster is different in several specific factors, consistent patterns have clearly been established that are common to most disasters, allowing for realistic planning. Every plan must also have a built-in flexibility to allow adaptation to unique contingencies of a specific event. Terrorist bombings, in view of their frequency, should be considered as the universal model for disaster management, and planning can be based on the well-established patterns of injury and mortality previously described. It is possible to anticipate resource needs and distribution from knowledge of the prognostic factors of these events that can be gleaned from the literature (Table 32.6).³² It is also possible to optimize the success of disaster plans by learning from the patterns and trends of major pitfalls described in past disasters (Table 32.7).⁷²

TABLE 32.5 **COMPLICATIONS**

EFFECT OF OVERTRIAGE ON SURGE CAPACITY

% OVERTRIAGE ^a	SURGE CAPACITY ^b	OVERTRIAGE LOAD ^c
0	4.7	0
25	4.6	1.6
50	3.8	3.8
75	2.7	8.1

^aPercentage of casualties arriving at hospital not requiring hospital care.

^bNumber of critically injured casualties per hour.

^cNumber of noncritically injured casualties per hour.

TABLE 32.6**RESULTS****PROGNOSTIC FACTORS THAT AFFECT THE CASUALTY OUTCOME FOR TERRORIST BOMBINGS**

Magnitude of explosion
Triage accuracy
Time interval to treatment
Anatomic injuries
Location
Confined space vs. open air
Rural vs. urban
Building collapse
Immediate presence of surgical capability

The Incident Command System has been widely adopted as the best organizational and functional scheme for a comprehensive and successful disaster response. The five major components of this system are command, planning, logistics, operations, and finance/administration. This integration of resources into a unified command has been shown to avoid the major barriers and to promote the most effective interaction of the several components of a disaster response.^{72,73}

It is essential that surgeons be integrally involved in disaster planning and management by participating in their local hospital disaster committee, their hospital disaster drills, and community disaster exercises. The care of trauma patients and rapid decision making for large numbers of patients are what surgeons are trained to do and what they regularly practice. In fact, U.S. trauma centers and the nationwide trauma systems should logically serve as the template for a national disaster response system in view of their extensive resources, collective expertise, and already established liaisons with most of the elements necessary in a disaster response (i.e., prehospital assets, search and rescue, air medical transport, law enforcement, fire services, public health, media, local and state government health services).⁷⁴⁻⁷⁶ It is also important that the results of a disaster be analyzed and reported in the surgical literature as the only means by which health care providers can be educated. This analysis also allows a postevent debriefing on the part of those involved in a disaster, which should result in a revision of the disaster plan to correct any deficiencies identified. These goals all require that an effective method of record keeping be in place to allow patient tracking and data accumulation during the disaster, from which a comprehensive analysis of results can be derived. A successful disaster response can be achieved only through intensive education, research, self-analysis, reassessment, and practice.

TABLE 32.7**COMPLICATIONS****MOST COMMON BARRIERS TO A SUCCESSFUL DISASTER RESPONSE**

Failure of communications
Security failures at the scene and hospital
Failure to designate authority and responsibility
Ineffective and inefficient system of medical care of casualties
Failure of original disaster plan
Failure to manage and control volunteers
Lack of education and training among responders

CHAPTER 33 ■ TRANSPLANTATION IMMUNOLOGY

JEFFREY L. PLATT AND MARILIA CASCALHO

KEY POINTS

- 1 Development of the vascular anastomosis and immunosuppression were the key technologic advances that allowed clinical application of transplantation.
- 2 The condition of the donor and ischemia and reperfusion of the transplant impact directly on grafts and on the immune response to grafts.
- 3 The genetic relationship between the recipient and the donor determine the outcome of a transplant, especially susceptibility to rejection.
- 4 Transplantation provokes immune responses by T cells and B cells.
- 5 Modern immunosuppressive agents and regimens effectively prevent acute rejection.
- 6 The impact of T-cell and B-cell responses on a graft depends to the greatest extent on whether a transplant consists of cells, tissues, or an organ.
- 7 Transplanted organs but not transplanted cells and tissues are susceptible to various types of humoral rejection; all transplants are susceptible to cellular rejection.
- 8 Chronic rejection is the most common cause of loss of organ transplants.

Transplantation refers to the transfer of living cells, tissues, or organs from one individual to another. Envisioned from a theoretical perspective throughout history, transplantation has been attempted surgically since the early years of the twentieth century. Today, transplantation is the preferred method to replace the function of the heart, lungs, kidneys, liver, and bone marrow and, in some circumstances, the islets of Langerhans of the pancreas. Applications may soon be expanded if transplantation of stem cells or the derivatives of stem cells become part of clinical practice. Transplants have shed light on such fundamental principles of biology and immunology as the genetic differences between individuals in a population, the principle that organs are integral biologic structures, the major histocompatibility complex, and tolerance. Many terms have been applied to transplants based on the genetic relationship between the source and recipient of transplants. Some of these terms are listed and defined in Table 33.1.

THE VASCULAR ANASTOMOSIS AND FIRST LESSONS OF TRANSPLANTATION

The field of clinical transplantation was launched by the advent of the vascular anastomosis. The development of surgical techniques for repair and anastomosis of blood vessels met a widely recognized and urgent need for repair of traumatic and surgical wounds.^{1,2} Development of the vascular anastomosis taught technical lessons such as the importance of asepsis and protection of vascular intimae. It taught that restoring blood flow could avert gangrene distal to a vascular lesion. It taught that some organs such as the kidney function as integral units (the kidney can be removed and reimplanted) and that function is not dependant on anatomic location (the kidney can be implanted in a heterotopic location). The greatest excitement was generated by the possibility that the vascular anastomosis might allow the replacement of a diseased or

1 injured organ with a healthy one. Ultimately, the vascular anastomosis was one of two advances critical to the clinical application of organ transplantation, the other advance being the discovery of immunosuppression.

Successful application of the vascular anastomosis for transplantation of the kidneys was reported by Alexis Carrel in 1908.² Carrel was awarded a Nobel Prize in 1912 for having developed the vascular anastomosis and using it to launch the field of transplantation. However, Carrel's collaborator, Charles Guthrie, actually perfected the technique of vascular suture, which Carrel applied.^{3,4,5}

The outcome of the first transplants is illustrated in Figure 33.1.⁵ Although Carrel claimed the transplants to be successful, all of the recipients died during the ensuing 5 weeks. This result contrasts with the outcome of transplants performed into the same animals from which the kidneys were harvested, termed *autografts*. These results illustrate several points. Organs transplanted into unrelated individuals (*allografts*) almost invariably fail, while organs transplanted into oneself or into a genetically identical recipient, an *isograft*, survive indefinitely. This chapter will consider the biologic reasons why transplanted tissues and organs fail.

INJURY FROM HARVESTING, ISCHEMIA-REPERFUSION, AND OTHER "TECHNICAL" PROBLEMS

- 2 The medical condition of the source of the transplant and the donor and the procedures associated with harvesting, preserving, transplanting, and reperfusion a graft influence the outcome of transplantation, sometimes profoundly.⁶ The surgical removal or "harvesting" of organs and tissues for transplantation, like any surgical procedure, damages cells and extracellular structures (Fig. 33.2). The utmost haste and meticulous technique cannot avoid completely this injury. Because these problems vary with the organ and tissue transplanted, we focus

TABLE 33.1

TERMINOLOGY OF TRANSPLANTATION

■ TERM	■ DEFINITION
Autograft	Transplant to oneself
Allograft	Transplant from one individual to another in a species
Homograft	Allograft
Isograft	Transplant to a genetically identical individual
Xenograft	Transplant from an individual of one species to an individual of another species
Heterograft	Xenograft

here on the properties and impact of ischemia-reperfusion injury common to all organs and tissues.

Severe surgical trauma, such as prolonged ischemia or failed anastomosis, can condemn an organ or tissue. Such severe injury may underlie some early deaths after transplantation illustrated in Figure 33.1 and described in Carrel’s seminal report.² Such technical failures are still observed, but fortunately far less often. The disruption of blood flow deprives tissues of oxygen and allows wastes to accumulate; physical injury triggers aggregation of platelets and activation of coagulation and complement cascades. Severe ischemia-reperfusion injury of organ and tissue transplants can cause immediate failure of grafts to function. Even mild ischemia-reperfusion injury activates endothelium and inflammatory cells, which in turn promote immunity to grafts. By means yet uncertain, ischemia-reperfusion injury may eventuate in changes over months and years, sometimes referred to as *chronic rejection*.

Ischemia-reperfusion injury refers to tissue damage seen after disruption and subsequent restoration of blood flow to a tissue or organ. The term reflects complexity of the pathogenesis; absence of flow causes some damage, restoration of flow causes

other damage. Ischemia-reperfusion injury to the heart (myocardial infarction) and brain (stroke) are leading causes of death and disability. Organs differ in the extent to which they are damaged by ischemia-reperfusion. Lung, liver, and heart are more susceptible than kidney. The risk of severe ischemia-reperfusion injury limits the time that organs can be “preserved” prior to transplantation and hence the matching of organs to the recipients most in need.

The mechanisms by which ischemia-reperfusion injures tissues remain uncertain. Table 33.2 lists some factors implicated in the pathogenesis of ischemia-reperfusion injury. Inhibition or absence of these factors can prevent or decrease ischemia-reperfusion injury. Since inhibition of many different factors decreases or eliminates ischemia-reperfusion injury, those factors must function in series or in a limiting way in parallel, with injury critically dependent on the sum of independent insults. How these factors orchestrate the pathology and pathophysiology of ischemia-reperfusion injury is a question of central importance in the field of transplantation.

The factors that initiate ischemia-reperfusion injury remain unclear and are the focus of much inquiry. Surgical harvesting deprives organs and tissues of the flow of blood. Severe injury and/or prolonged deprivation of blood cause changes in small blood vessels that prevent re-establishment of perfusion, a condition referred to as *no reflow*, and directly cause necrosis.⁷ Mild injury and shorter periods of ischemia cause transient changes in structure and function. Deprivation of oxygen might initiate many of the reversible changes in ischemia-reperfusion injury.⁸ Reperfusion of a graft also contributes to tissue injury, perhaps to a greater extent than ischemia.

Nearly every factor that contributes to tissue injury can also protect against it.^{9,10} For example, activation of complement in subtoxic amounts causes cells to acquire resistance to toxic amounts of complement.¹¹ Similarly, while inhibiting interleukin-1 (IL-1) decreases ischemia-reperfusion injury, treatment with IL-1 in advance of reperfusion protects against damage.^{12,13} This antithesis of injury and protection suggests that ischemia-reperfusion injury may cause damage in some circumstances but may be protective in others. As only one example, ischemia-reperfusion injury may help to sequester the

FIGURE 33.1. Method (A) and outcome (B) of the initial “successful” transplants reported by Carrel in 1908.² All recipients died over a period of weeks. In contrast, a few autografts performed by the same surgeon functioned for years. The difference between the outcome of autografts and allografts illustrates the preeminence of the immunologic barrier to transplantation. ([A] from Carrel A. © Originally published in *The Journal of Experimental Medicine*. 1908;10:98–140.)

FIGURE 33.2. Impact of ischemia-reperfusion on the structure of a graft. The figure depicts heparan sulfate, a sugar that supports most of the normal functions of blood vessels, by silver staining in a normal heart (left) and in hearts transplanted heterotopically into genetically identical guinea pigs (middle and right). The micrograph on the right is from a recipient in which complement was inhibited by treatment with cobra venom factor (CVF). The figure shows that transplantation under optimal surgical conditions causes loss of all detectable heparan sulfate in a complement-dependant manner.

microorganisms through vasoconstriction and coagulation and at the same time may allow activation of antigen-presenting cells and delivery to lymphoid organs, thus promoting host defense.¹⁴ Because the factors contributing to ischemia-reperfusion also contribute to tissue repair and host defense, the solution to the problem of reperfusion injury may not reside in complete inhibition of the processes activated by it.

GENETIC DETERMINANTS

- 3 The genetic relationship between the source (donor) and the recipient determines the fate of transplants that survive ischemia-reperfusion injury and technical complications of the procedure. The nature of this genetic relationship, termed *histocompatibility*, occupies a central place in the field of transplantation. Because transplants with novel genetic properties may soon enter practice, we consider in some detail the classic rules governing acceptance and failure of grafts.

Evidence for the importance of genetics in the fate of transplants emerged in the early years of the twentieth century. C.O. Jensen, a Danish biologist, discovered that tumors arising in an inbred strain of mouse could be maintained by transplanting pieces of tumor tissue between members of that strain; however, pieces of tumor transplanted into common mice would grow for a period of days and then regress and disappear. Transplanted into a mouse in which the tumor had previously regressed, the tumor would disappear almost immediately.

TABLE 33.2

FACTORS CONTRIBUTING TO ISCHEMIA-REPERFUSION INJURY

■ FACTOR	■ MECHANISM
Hypoxia	Hypoxia-inducible factor
Complement	Senses injury; activates endothelium and leukocytes
Natural antibodies	Activate complement
Oxidants	Activate endothelium and damage cells
Apoptosis	Disrupts endothelium
Toll-like receptors	Activates endothelium and leukocytes
Cell adhesion molecules	Facilitate leukocyte migration
T cells	Unknown

Jensen speculated that regression of the tumor might be caused by immunity, and his observations sparked efforts in a number of laboratories to generate resistance to tumors by the transfer of serum from resistant mice. These efforts were futile and, Peter Medawar, reflecting on this period, later commented that “nearly everyone who supposed that he was using transplantation to study tumors was in fact using tumors to study transplantation—not always to very good effect.”¹⁵

Jensen’s contemporary, Leo Loeb, observed that spontaneous mammary adenocarcinomas in Japanese “waltzing” mice, so named because of a neurologic defect that made them twirl when stimulated, survived transplantation and grew in waltzing mice but never in mice of other stocks.¹⁶ Tumors from waltzing mice grew in offspring of crosses between waltzing mice and other strains and thus appeared to be governed by the “rules” of Mendelian inheritance.¹⁷ Tumors would not grow in mice of the F2 generation or in mice derived by crossing F1 with the resistant parent. If susceptibility to the tumor was conferred by a single genetic locus, then three fourths of the F2 generation and one half of the backcrosses should have been susceptible. This observation refuted Mendelian inheritance. From a large number of matings, a small fraction of the F2 generation and of backcrosses accepted the tumors, indicating that acceptance of tumors was governed by multiple independently segregating codominant traits.^{18,19}

Investigators used congenic strains to explore in detail the role of histocompatibility or “H” genes in tumor transplantation (Fig. 33.3). Genes varied in their impact on the outcome of transplants, and the “strength” of different H genes was a specific feature of the gene. Incompatibility of strong histocompatibility genes, now known to be products of the major histocompatibility complex, inevitably caused resistance to tumors. Incompatibility of weak histocompatibility genes, now called *minor histocompatibility genes*, led sometimes but not always to resistance to tumors. Moreover, when incompatibility of weak histocompatibility genes led to tumor resistance, the tumors would often grow to larger size and over a longer period of time before resistance was manifest. Immunization with tissue incompatible for weak histocompatibility genes sometimes could make the immunized mouse resist tumors as fully as if the tumors carried strong histocompatibility disparities. Immunity to tumors was akin to immunity to normal tissues.²⁰ Histocompatibility, defined genetically, corresponds with immune responses and immunity aroused by transplantation of foreign tumors also recognizes nonmalignant cells of the same foreign source.²¹

The H-2 locus is a strong histocompatibility locus because tumors disparate at H-2 always regress and transplants disparate at H-2 are always rejected and the rejection reaction proceeds rapidly.^{22,23} The strong histocompatibility locus was

FIGURE 33.3. The outcome of transplants incompatible at strong and weak histocompatibility loci. The figure shows that incompatibility of strong histocompatibility genes causes rapid and universal rejection of allografts. Incompatibility of weak histocompatibility genes causes rejection to occur in some but not all transplants and at a relatively slow rate. Prior exposure to a transplant incompatible for a weak gene causes the response to be universal and more rapid. The locus of the strong histocompatibility genes is called the major histocompatibility complex.

later found to be a complex of genes called the *major histocompatibility complex* (MHC). Transplants matched for MHC might still undergo rejection, albeit at a slower tempo; this type of rejection was attributed to “weaker” histocompatibility antigens, later called “minor” antigens.

In 1958, Jean Dausset discovered that human patients who had received multiple transfusions of blood were subject to transfusion reactions, and contained in their serum antibodies specific for leukocyte alloantigens.²⁴ These antigens, ultimately called *human leukocyte antigens* (HLAs), were encoded by genes analogous to the murine H-2 genes.

The field of histocompatibility has struggled to address the nature of the genetic determinants of tissue individuality, the factors that condition recipient immune responses to foreign tissues, and the mechanisms mediating those responses. A central question has been whether antigens encoded by MHC (“MHC antigens”) function only as passive targets of immune responses or whether MHC antigens participate in some way in the physiology of the immune system.²⁵ Another question has been what distinguishes the “strong” histocompatibility barrier posed by antigens encoded by MHC versus the weaker barrier posed by minor antigens. Yet another question concerned the nature of MHC genes and the proteins they encode that enable this system to confer uniqueness to each member of an outbred population. Only recently have answers to these questions emerged and the biologic role of histocompatibility determinants in the initiation and regulation of immune responses in normal animals been determined.

IMMUNITY AND THE REJECTION OF TRANSPLANTS

Initial efforts to connect immunity with the destruction of transplants failed. This failure stemmed from the belief that immunity was manifest only by production of antibodies and every effort to transfer immunity to transplants with immune serum failed. In the early 1940s, Landsteiner and Chase demonstrated that the cells but not the serum of sensitized animals could transfer delayed-type hypersensitivity reactions from one individual to another.²⁶ The existence of cellular immunity and pertinence for the rejection of transplants were appreciated by the demonstration that immunity to a transplant can be transferred by cells.²⁷ How the lymphoid cells, later called “T” lymphocytes because they originate in the thymus, might recognize foreign tissues became an issue of widespread interest. Those who studied transplants also failed to appreciate that antibodies have far more impact on organ grafts than on cell and tissue grafts.

The conceptual hurdles to connecting immunity with the failure of transplants were overcome by Thomas Gibson and

Peter Medawar in 1943.²⁸ Skin allografts were thought to fail either because of local incompatibility leading to inflammation or because of immunity. Since immunity was thought only to be humoral, and since transfer of immune sera had no impact on grafts, immunity was not the favored explanation. Gibson, a surgeon, and Medawar, a biologist, asked whether immunity might cause the failure of skin grafts between different individuals (allografts). The question was urgent because surgeons were called upon to treat extensive burn wounds and skin grafting could prevent the loss of water, infection, and contractures caused by such wounds. Gibson and Medawar carried out a series of skin grafts on one human subject with extensive burns. A “first set” of skin grafts from the patient herself (autografts) and from the patient’s brother (allografts) was performed. On the 10th day, the autografts and allografts appeared normal to the eye but biopsies revealed inflammation in the allografts. On the 15th day, a “second set” of autografts and allografts was performed. On the 23rd day, the first set of autografts appeared normal but the first set of allografts had deteriorated markedly. The second set of allografts (now in their eighth day) had not taken; some were detached and some appeared white and not perfused. The fate of the second set of allografts, accelerated destruction, pointed to immunity rather than a local reaction as the cause of graft loss. Medawar followed up on this initial clinical study with extensive work in rabbits.^{29–31} This work confirmed irrefutably that the reaction to transplantation of foreign tissue causes the destruction of allografts and has the fundamental characteristics of an immune response. The reaction (a) is systemic, (b) is specific (e.g., the second set reaction does not afflict third-party grafts), (c) is generalized (e.g., the same reaction aroused by tumors is aroused by skin), and (d) exhibits memory. The recipient thus rejects the graft and the immune system is the vehicle of that process.

CHARACTERISTICS OF TRANSPLANT IMMUNITY

If the first 40 years of transplantation (~1906–1946) proved that Mendelian genetics and immunity govern the fate of transplants the exact mechanisms of governance are still incompletely understood. Both T lymphocytes and B lymphocytes respond to transplantation, but the impact of these cells and their products varies profoundly depending on whether the transplant is an intact organ, which is attacked by both T cells and antibodies, or cells and tissues, which are attacked mainly by T cells (See Impact on Transplants below). In many cases clinicians define immune responses to transplantation based on graft injury or rejection. While the presence of graft injury may prove the existence of a destructive immune response, all immune responses to transplantation are not destructive and some may actually protect grafts.

PRODUCTS OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

The immune response to products of the major histocompatibility complex (i.e., MHC) dominates the immune response to transplantation, except transplants between some siblings or inbred animals matched at the MHC.^{21,22,24,32} Antigens encoded by the MHC dominate transplant immunity in part because the antigens are highly polymorphic, meaning all individuals in a species can be assumed to differ from all others at one or more loci of the MHC, and be highly antigenic.

Major Histocompatibility Complex Class I Molecules

MHC class I molecules consist of a 45-kD α chain and β_2 -microglobulin, a 12-kD glycoprotein not encoded by the MHC complex (Fig. 33.4A). The MHC class I molecule has four extracellular domains, a transmembrane region, and a cytoplasmic “tail.” Each MHC class I molecule has a groove that harbors an antigenic peptide. Correct folding of the class I MHC proteins depends on the presence of the peptide. The peptide and polymorphic regions of the α_1 and α_2 domains bind to the T-cell receptor. A nonpolymorphic region of the α_3 domain binds to CD8.

The peptides presented by MHC class I molecules are 8 to 10 amino acids in length and join the MHC class I molecule during assembly in the endoplasmic reticulum.³³ The peptides derive from degradation of cytoplasmic proteins by proteasomes made up of low-molecular-proteins encoded in the class II region of HLA in close linkage with genes encoding the peptide transporters for both class I and class II molecules and by other proteases. These transporters carry the peptides into the endoplasmic reticulum where the class I assembly takes place.²⁴ The major transporter of peptide destined to associate

with MHC class I molecules is the *transporter associated with antigen processing* (TAP). The ability of the TAP to attach to a peptide determines in part the immunogenicity of the peptide. In the endoplasmic reticulum, the peptide is affixed to MHC class I molecules by a complex of proteins called the *peptide-loading complex*. This complex can promote exchange of bound peptides, further determining immunogenicity.

The peptides bound to MHC class I molecules in most cells originate either from endogenous proteins or proteins produced by viruses and other intracellular organisms. This limitation would seem to ensure that the cellular targets of cytotoxic T cells, which recognize MHC class I, include only those cells harboring intracellular microorganisms. However, this rule is violated by antigen-presenting cells, which can transform peptides derived from exogenous proteins into MHC class I molecules. This process is called *cross-presentation* (or *cross-priming*). Cross-presentation may occur in several ways; most involve the fusion of endosomes containing the products of phagocytosis, both proteins and cellular fragments, with the endoplasmic reticulum. Cross-presentation is essential for the development of cytotoxic responses against tumor cells, allogeneic cell transplants, and cells infected by viruses.

Major Histocompatibility Complex Class II Molecules

MHC class II molecules are heterodimers consisting of a 34-kD α chain and 29-kD β chain (Fig. 33.4B). MHC class II molecules are expressed mainly by specialized antigen-presenting cells such as macrophages and dendritic cells. In humans, endothelial cells also express MHC class II molecules. MHC class II molecules have four extracellular domains, a transmembrane region, and a cytoplasmic “tail.” The tertiary structure of MHC class II antigens provides a pocket or antigen-binding cleft between the two polypeptide chains.³⁴ The assembly of MHC class II molecules in the endoplasmic reticulum requires

FIGURE 33.4. A: Human leukocyte antigen (HLA) class I molecule. The polymorphic heavy chain (45 kD) of the class I polypeptide is non-covalently bound to the invariant light chain, β_2 -microglobulin (12 kD). The heavy chain consists of five domains—three extracellular domains (α_1 , α_2 , and α_3), a transmembrane domain, and a cytoplasmic domain. The α_1 and α_2 domains contain the most polymorphic residues responsible for antigen binding and form the side walls of the peptide-binding groove; the transmembrane portion anchors the molecule to the plasma membrane; and the β_2 -microglobulin stabilizes the conformation of the extracellular domains. B: Human leukocyte antigen (HLA) class II molecule. The two chains, α (29 kD) and β (34 kD), are noncovalently associated and are made up of four domains—two extracellular domains, a transmembrane domain, and a cytoplasmic domain. Most of the allelic variance is contained in the β chain. The peptide-binding site is believed to be in the groove between the α_1 and β_1 domains.

FIGURE 33.5. T-cell receptor (TCR) complex in the cell membrane composed of TCR $\alpha\beta$, CD3, CD4, and CD8 chains.

the presence of *invariant chain* or *Ii*, which stabilizes the tertiary structure until it is replaced by a peptide. The invariant chain also directs the traffic of MHC class II proteins from the endoplasmic reticulum to a specialized endosomal compartment known as the MHC class II compartment. There, the invariant chain is degraded, leaving *class II-associated invariant chain peptide* (CLIP) in the peptide-binding groove. CLIP is replaced by peptides of 12 to 24 amino acids, the replacement being facilitated by HLA-DM.^{35,36}

The peptides bound to MHC class II molecules originate with intact cells, cellular debris, and proteins taken up by phagocytosis into phagosomes.³⁷ Phagosomes fuse with lysosomes and the contents are degraded. Peptides generated in phagolysosomes vary greatly in propensity for loading in MHC class II. Not only is the size of the peptide important, but also the presence of certain amino acids at critical points, which allow binding to the antigen-binding cleft. So important is this discrimination of peptides that the genes encoding MHC class II were originally called “immune response genes.” MHC class II antigens lacking a peptide are not expressed on the cell surface.³⁸ Absence of “free” MHC class II antigens ensures that peptides in the extracellular environment are not inadvertently presented.

T-cell Receptors

T cells recognize foreign antigens via cell surface glycoproteins called *T-cell antigen receptors* (TCRs). The TCR is a heterodimer consisting of α and β chains, each approximately 40 to 45 kD and resembling immunoglobulins in three-dimensional structure (Fig. 33.5). TCRs reside in complexes with co-receptor proteins including CD3 and CD4 or CD8 that facilitate cellular signaling. While TCRs resemble immunoglobulins, they do not bind to “free” antigens as immunoglobulins do but only bind to antigens that are associated with MHC class I or class II molecules. TCR genes are assembled in T-cell precursors in the thymus by recombination of a constant region gene

segment C with one each of a number of V, D, and J gene segments in the case of β chains and V and J segments in the case of α chains. Much of the diversity of the TCR repertoire is engendered by the inexact selection of the ends of the segments to be so spliced (i.e., from junctional diversity). The joining of various V, D, and J segments to form a T-cell antigen receptor gene could yield 10^{12} to 10^{16} specificities. However, from the repertoire of cells bearing TCRs actually assembled ($\sim 10^{12}$ different cells), a much smaller repertoire ($\sim 10^9$), which can bind to self-MHC proteins plus peptide, is “selected” to proceed toward maturity. This process ensures that all T cells can recognize self-MHC. Fashioning of the final T-cell repertoire in the thymus is also based on the general rule that the T cells that recognize peptides complexed with MHC class II molecules express CD4 glycoproteins; T cells that recognize MHC class I molecules express CD8 glycoproteins. The final T-cell repertoire is also fashioned by elimination of thymocytes with TCRs that bind too aggressively to self-MHC, a process called *negative selection*.

ANTIGEN PROCESSING AND PRESENTATION

Recognition of foreign antigen by T cells begins with the processing and presentation of antigen by *antigen-presenting cells*.³⁹ Phagocytic cells of all types, especially dendritic cells and B cells, process and present antigen. Antigen-presenting cells engulf and digest antigens (Fig. 33.6). Because cells generate many different peptides from endogenous proteins and proteins ingested into cells, relatively few peptides from any given source and of any given sequence will be presented on the cell surface at any point in time. Since activation of a T cell requires at least 200 peptides of a given type to be presented, effective presentation of peptide to a T cell capable of recognizing it is highly improbable.⁴⁰ Thus, under normal conditions, antigen-presenting cells do not effectively present peptides in association with MHC. Effective presentation of antigenic peptides requires activation of antigen-presenting cells, typically by cytokines or products of tissue injury. Activated antigen-presenting cells migrate to lymph nodes, the architecture of which brings T cells and antigen together at the same place and the same time, heightening expression levels of MHC class I and class II proteins and increasing peptide stability in those protein complexes.⁴¹ Activated antigen-presenting cells also express costimulatory molecules such as CD80 and CD86 and produce cytokines that provide additional signals to T cells.

T-CELL ACTIVATION

Activation of T cells generally requires two signals, one delivered by the T-cell antigen receptor and proteins of the TCR complex and one by a *costimulatory receptor*.⁴² The binding of the TCR to MHC molecules is enhanced by CD8 for MHC class I molecules and by CD4 for MHC class II molecules. CD8 and CD4 in complex with TCR deliver signals that amplify TCR stimulation. Besides signals generated by the TCR complex, T cells receive costimulatory signals from receptors such as CD28. Costimulatory signals overlap and in part complement the signals generated by the antigen receptor complex.^{43,44} Signals delivered by the antigen receptor and by costimulatory receptors can be suppressed by stimulation of *controlling receptors* such as cytotoxic T-lymphocyte antigen-4 (CTLA-4). Both types of signals are modified further by other signals, such as those delivered by cytokines.

The biochemistry of T-cell activation and control is complex, but the biologic impact can be summarized as follows. Moderate signals delivered through the TCR complex in the

FIGURE 33.6. Antigen processing and presentation. Endogenously synthesized or intracellular proteins (e.g., viral gene products) are degraded into peptides that are transported to the endoplasmic reticulum. These peptides bind to class I major histocompatibility complex (MHC) molecules and are transported to the surface of the antigen-presenting cell. CD8+ T cells recognize the foreign peptide bound to class I MHC by way of the T-cell receptor complex. Exogenous antigen (e.g., bacterial) is endocytosed and broken down into peptide fragments in endosomes. Class II molecules are transported to the endosome in association with the invariant chain, bound to the peptide, and delivered to the surface of the antigen-presenting cell, where they are recognized by CD4+ cells.

presence of costimulatory receptors activate T cells, leading to proliferation and manifestation of effector functions such as secretion of cytokines and cytotoxicity. Moderate signals delivered through the TCR alone induce anergy, a condition in which T cells are transiently inured to delivery of full signaling. Strong signals delivered through the TCR can activate T cells without costimulation. Some allospecific T cells may be activated in this way. Finally, the survival of mature T cells depends on frequent weak signaling through the TCR; such signals reflect interaction of the TCR with MHC plus self-peptide.

Besides the specific signals delivered to T cells, the survival, activation, and apoptosis of T cells depend on the total level of signaling. Thus, the sum of many weak signals might evoke an activating response like a few strong signals. The impact of many weak signals may be especially pertinent in transplantation when T cells confront allogeneic antigen-presenting cells. The properties of the stimulated lymphocyte thus depend not only on the nature and strength of the antigenic stimulus, but also on the nature and strength of other sources of stimulation and the microenvironment in which the lymphocyte resides. For example, activation of T cells in the blood requires much more potent stimulation than activation of T cells in lymphoid tissues. Activation of T cells in lymphoid tissues may lead to a full immunologic response, whereas activation in the blood

may lead to a limited response or to tolerance. To understand how T cells become activated and what governs the response of T cells, one must consider how T cells recognize antigen, the function of *accessory cells* that present antigen to T cells, and the surrounding microenvironment.

Some T cells activated by alloantigen can directly attack a graft. However, most T cells so activated provide “help” for other leukocytes that will exert the attack. These other leukocytes include B cells, CD4+ effector cells, CD8+ cytotoxic cells, and activated phagocytes like APC (Fig. 33.7).

IMMUNOLOGIC MEMORY

Protective immune responses by T cells and B cells generally reflect immunologic memory. The first encounter with foreign antigen may or may not activate naïve T cells, with activation occurring over an extended period of time (weeks). Consequently, defense against microorganisms and toxins on first encounter depends on innate immunity. Defense against subsequent encounters with microorganisms and toxins can be dominated by *immunologic memory*, which is more rapid, specific, and effective than innate immunity. The vigorous and reliable memory response to minor transplantation antigens was described earlier. For cellular immunity, memory resides

FIGURE 33.7. Central paradigm for cellular initiation of an immune response. CD4+ T cells respond to appropriately presented antigen on antigen-presenting cells (APCs) and in turn help other T cells, B cells, and APCs.

in *memory T cells*. Memory T cells have several properties that make them especially effective. Memory T cells exist in larger numbers per clone than naïve T cells and migrate throughout the body rather than dwelling in lymphoid organs like naïve T cells. Memory T cells can be activated by weak stimulation of the TCR with little or no costimulation. Memory T cells survive for long periods of time, possibly years, without exposure to antigen. Although it protects against infectious organisms, the memory T-cell response poses a considerable hurdle to successful transplantation: those with memory responses are especially prone to accelerated cellular and humoral rejection. Because primary immune responses to allogeneic stimulation are so powerful, detecting memory responses can be challenging. Allospecific antibodies against a transplant donor suggest that such a response might exist.

UNIQUE FEATURES OF THE IMMUNE RESPONSE TO TRANSPLANTATION

While recognition by T cells of foreign histocompatibility antigens might offer one explanation for the specificity of allogeneic responses, how transplants activate T cells is not so obvious. Under the best conditions, transplantation generates little costimulation. Some ischemia may be inevitable, but it is not clear that this amount would suffice to induce immunity rather than tolerance. Experimental models in which costimulation is entirely lacking reveal no diminution in rejection.⁴⁵ Thus, activation of T cells by transplants appears to violate rules governing immunity versus tolerance.

Activation of T cells by allogeneic cells poses another challenge. T cells recognize immunizing antigens if they are expressed by histocompatible cells.^{25,46} Foreign antigens form a complex with self-MHC molecules, and this complex is recognized as *altered self*. Such a model allows allogeneic MHC molecules to serve as “altered self.” This concept has been validated by the determination of the three-dimensional structure of the TCR in conjunction with allogeneic MHC. Thus, histocompatibility antigens are no longer thought of as mere markers of individuality but as cellular tools for the processing of antigenic peptides and the transmission of information between sets of functionally distinct immune cells. The function of MHC molecules in antigen presentation is one element of the central role of MHC antigens’ alloimmune responses.

TABLE 33.3

COMPARISON OF IMMUNE RESPONSE TO AN ALLOGRAFT WITH IMMUNE RESPONSE TO A MICROORGANISM

	■ ALLOGRAFT	■ MICROORGANISM (BCG)
Frequency of response	100%	50%
Frequency of T cells	Up to 1/10	~1/100,000
Kinetics of immunity	8–14 d	3–6 wk
Impact on tissue	Destruction	Minimal

While the immune response to transplantation exhibits features typical of all immune responses (generalized, systemic, specific, and characterized by memory), the immune response to transplantation also exhibits features that set it apart from other adaptive immune responses (Table 33.3). Considering how very limited the genetic diversity within a species is, and considering that the immune system probably evolved to protect against microbial organisms, one might predict that immune responses to transplants would be idiosyncratic and weak in comparison to immune responses to microorganisms. But such a prediction proves wrong. The immune response to transplantation is universal (occurring in every unmanipulated recipient), rapid, and quite severely destructive.⁴⁷ In contrast, immune responses to bacteria, viruses, fungi, vaccines, and other antigens, including minor histocompatibility antigens, occur sporadically, over periods of weeks or months, and do not generally destroy the targeted cells. The difference between the immune response to allografts and to all other antigenic challenges could reflect the peculiar way in which antigens encoded by the major histocompatibility complex are presented, or it could reflect unanticipated immunologic memory.^{48,49}

The mechanism by which T cells recognize allogeneic cells might explain the universal, rapid, and highly destructive allogeneic response. T cells can recognize allogeneic cells “directly”; T cells recognize intact allogeneic MHC expressed on allogeneic antigen-presenting cells. By direct recognition, a T cell can engage a large fraction of a given MHC on antigen-presenting cells.^{50,51} Hence, direct recognition activates up to 30% of T cells.⁵² In contrast, T cells recognize other antigens, such as toxins and bacterial and viral proteins, as degraded foreign peptides associated with MHC on autologous antigen-presenting cells. When T cells indirectly recognize antigen on autologous antigen-presenting cells, only a small fraction of MHC complexes on the autologous cells contain a given peptide. Hence, indirect recognition activates only a small fraction of 1% of T cells; in some cases no activation ensues.

Grafts consisting of allogeneic cells and tissues are fed by blood vessels of the recipient, and the immunologic reaction seems to be directed mainly against these blood vessels.^{52–54} Recognition of these blood vessels must involve the indirect pathway. Yet these grafts are rejected universally, rapidly, and severely. Eliminating allogeneic MHC from the surface of all donor cells does not prevent or slow the course of allograft rejection.⁵⁵

If peptides of allogeneic MHC presented indirectly can evenuate powerful rejection reactions, then the immune system might recognize peptides of allogeneic MHC differently than other proteins. The immune system is predisposed to respond aggressively to allogeneic MHC.⁵⁵ Heightened immunogenicity of MHC-derived peptides indicates that peptides from MHC efficiently load on MHC complexes.^{56,57} MHC with MHC-derived peptides also interacts distinctly with T-cell receptors.

Besides efficient loading, peptides from MHC might be recognized in some special way. This idea may explain the distinct structure of TcRs bound to MHC-peptide complexes.

As still another explanation for the universal, rapid, and severe response to allotransplantation, one might postulate that the allogeneic response is actually a manifestation of immunologic memory. Generally, a protective response occurs weeks and sometimes months after the first exposure to antigen, if it occurs at all, and full protection is only exhibited upon re-exposure to antigen. On the other hand, responses on first exposure to cells bearing allogeneic MHC can be detected within a few days. The speed and intensity of the allogeneic response thus resembles the speed and intensity of the response on re-exposure to antigen. Consistent with this possibility, many of the T cells that respond to allogeneic cells in human adults are memory T cells.⁵⁸ This explanation would place alloimmune responses within the framework of conventional immune responses. Some T-cell clones for peptides of cytomegalovirus and intestinal flora also respond to allogeneic MHC. Allogeneic grafts in the newborn sometimes generate immunity and sometimes do not. Consistent with the concept, newborn mice do not reject tumor grafts acutely but can still be primed to generate second set responses, as if the antigens were minor rather than major.⁶⁰

One practical implication of the difference in antigen recognition in alloimmune versus conventional responses is that alloimmune responses can be detected in cell cultures if allogeneic antigen-presenting cells are mixed with allogeneic T cells. For conventional antigens, primary responses are not detected in cell culture systems; only “memory” responses can be detected in this way.

The rapid kinetics of alloimmune responses probably reflects several factors. To the extent that peptides play a nominal role as antigenic targets, antigen-presenting cells of the donor are fully able to evoke alloimmune responses without antigen uptake processing and presentation. The large number of cells committed to alloimmune responses limits the amount of T-cell proliferation needed before a sizable response is achieved. Especially important, the effector functions of the alloimmune response follow directly from activation of naïve T-cells.

REGULATION OF ALLOIMMUNE RESPONSES

The immune system must potentially recognize all microorganisms, every species of animal and plant, toxins of many types, and cells with histocompatibility antigens foreign at one or only a few amino acids. Given this diversity of recognition and destructiveness, how autoreactivity is avoided has been a question of importance for more than 100 years.^{61,62} Freemartins are fraternal twins in cattle.⁶³ Freemartins have two kinds of erythrocytes, those that bear blood group antigens of autologous hematopoietic cells and those that bear the blood group antigens of the twin, thus making the freemartin hematopoietic chimeras. The existence of such chimerism shows that blood and hematopoietic precursor cells have been exchanged between twins sharing the same placenta. Such chimerism results from the failure to mount an immunologic response against the “foreign” blood cells; this failure is evidence of induced acceptance of a genetically distinct intrauterine graft, in other words, tolerance.⁶⁴ Thus, the discrimination between self and non-self is learned and not just inherited.

Today, one can think of tolerance at molecular, cellular, and systemic levels, yet the mechanism that avoids self-reactivity, or at least injury from self-reactivity, is incompletely known. A few aspects pertinent to transplantation immunology are mentioned and are summarized in Table 33.4. For T cells, the first and most important steps in avoiding self-reactivity take place in the thymus. Positive selection ensures that thymocytes bearing receptors that bind to anything other than MHC die. Negative selection destroys thymocytes that recognize self-MHC,

TABLE 33.4

MECHANISMS OF PERIPHERAL TOLERANCE

MECHANISM	EXAMPLE
Shape the repertoire to eliminate reactive lymphocytes	Peripheral deletion
Conditional responses	Anergy
Suppression	Regulatory T cells
Prevent immune-mediated injury	Accommodation

and thymocytes that react to self-peptides too strongly also die. Tolerance of T cells during development in the thymus is referred to as *central tolerance*.

Some T cells capable of recognizing self-antigen inevitably emerge from the thymus. What prevents these cells from reacting with self has been the focus of much investigation. B cells stimulated only through the antigen receptor are not activated, and these cells are anergic.⁶⁵ B cells stimulated through the antigen receptor and by a second receptor are fully activated. Thus, activation of lymphocytes is conditional. A lymphocyte confronted with self-antigen without a second stimulus might become anergic and ultimately die; this process could shape the lymphocyte repertoire functionally and structurally to avoid self-responses. This concept of conditional responses has been supported by discovery of receptors such as CTLA-4 that deliver signals that suppress lymphocyte responses. Advances in understanding the function of antigen-presenting cells have further enriched the concept. Antigen-presenting cells confronting conditions of tissue injury heighten expression of MHC, express peptides enduringly, and express costimulatory agonists.⁶⁶ Thus, the concept of conditional responses of T cells can be used to explain how the immune system discriminates self from non-self.⁶⁷

Anergy and conditional signaling cannot explain why transplant recipients do not become tolerant to their grafts. Vigorous immune responses are aroused by transplants under conditions in which danger signals are absent, and normal individuals suffer many small traumas every day without arousing autoimmunity to antigens in damaged tissue. Conditional immunity must depend on other controls.

Transplant immunologists in the 1970s and 1980s found that establishment of a graft for a period of time was associated with the development of suppressor cells. Perhaps lymphocytes could themselves suppress immune responses to self. This idea was not widely embraced until the 1990s, when T cells with a specific phenotype (CD25+) and functional properties (the cells proliferated slowly and did not exert effector properties) were found. The cells were called *regulatory T cells*. As further support for this mechanism, a transcription factor, foxP3, was found characteristically in these cells and was found to be essential for their function. Unfortunately, some of the immunosuppression regimens impair the function of regulatory T cells.⁶⁸

If no theory of tolerance fully explains the lack of toxicity from self-recognition, a theory directed at the targets of immunity might do so. In the 1980s, a few transplants were performed across ABO blood group barriers in recipients temporarily depleted of anti-blood group antibodies.^{69–71} Contrary to expectations, these transplants continued to function after antibodies specific for blood groups carried by the grafts returned to the circulation. The transplants were found to survive because they had acquired resistance to injury by antibody and complement.⁷² This resistance was called *accommodation*.⁷³ The concept of accommodation has been extended to protection of tissues from T cells and inflammation.⁷³ If the immune system avoids self-reactivity imperfectly, cells and tissues have a way of avoiding immune-mediated injury.

Accommodation may yet prove integral to defend against invasive organisms.

PREVENTING AND TREATING TRANSPLANT REJECTION

Matching Histocompatibility Genes

Although the products of the major histocompatibility locus are extraordinarily polymorphic, MHC genes, located on the short arm of chromosome 6, can be matched. If the source and recipient are related, for example, a brother and sister, the MHC can potentially be identical. If the source and recipient are unrelated, typically if a deceased donor is the source, HLA type of both can be determined at various levels of approximation.⁷⁴ HLA typing was once performed by serology using sera of known specificity. Presently, MHC genes are identified using DNA amplified by polymerase chain reaction. Several methods are used to determine HLA-A, -B, and -DR at various levels of resolution, including sequencing of the most variable regions as necessary.

One might expect that matching a donor and recipient for MHC would minimize alloimmune responses and improve the outcome of transplantation, potentially allowing transplantation without use of immunosuppressive drugs. Consistent with this possibility, surveys in the 1980s showed that HLA compatibility improved the outcome of organ transplantation.^{75–77} HLA matching takes time, thus lengthening the period before harvesting of organs or increasing ischemia-reperfusion injury. HLA matching also decreases the discretion of the clinician to find the best organ independent of HLA for each recipient. For example, matching might eclipse such considerations as matching for size or presence of viruses such as cytomegalovirus in the donor and recipient. Further, the benefit of matching is also decreased by improvements in immunosuppressive drugs.

Even where full matching of MHC can be accomplished, as in transplants between HLA-matched siblings, immunosuppressive therapy is still needed. What accounts for rejection of MHC-compatible grafts? Even with MHC typing performed by high-resolution methods, MHC sequences are not fully determined and may differ between the donor and recipient. If the donor of the transplant is infected with a virus, such as cytomegalovirus, that virus may be recognized as an alloantigen, generating an alloimmune-like response. Grafts matched with the recipient for MHC are still unmatched for other histocompatibility antigens because every protein exists as an allotype, and thus might potentially arouse an alloimmune response. In allotransplantation of the cornea, matching may actually increase the risk and/or severity of rejection, presumably because cornea antigens are presented through the indirect pathway in which alloantigen is presented as a peptide on self-MHC. With the indirect pathway, antigen presentation is best using self-MHC to present foreign peptide. To what extent this counterintuitive explanation—better matching worsens graft outcome owing to better antigen presentation—applies in cell and tissue transplantation is yet to be determined.

Besides determining HLA type, histocompatibility laboratories test would-be recipients of transplants for alloreactive antibodies. Three types of assays are performed.

The cross match tests the serum of a recipient for antibodies against a particular donor. The cross match can be performed by applying serum of the recipient to cells of the donor and testing for complement-mediated lysis or for binding by fluorescent-activated cell sorting (FACS). A strongly positive cross match indicates significant risk of hyperacute rejection, and is an absolute contraindication to transplantation.⁷⁸ The FACS cross match test can be quite sensitive, and the meaning of a weakly positive cross match is a current subject of debate.

The panel reactive antibody (PRA) test tests the serum of the recipient for antibodies against a panel of cells or antigen targets representing the broad population of potential donors. This test predicts how difficult the effort to find a cross match—negative donor for a given recipient will be. The test also predicts the risk of rejection in general, since the recipient with antibodies against many potential donors is more likely to mount a strong immune response to any transplant.

The blood type of the donor and recipient is determined. Where possible, donor and recipient are matched for ABO antigens.

IMMUNOSUPPRESSION FOR TRANSPLANTATION

Transplantation of organs and tissues in clinical subjects was attempted at various times during the first five decades of the twentieth century. With the exception of a few kidneys transplanted between identical twins, these clinical allografts always failed.⁷⁹ What allowed transplantation to succeed was the development of immunosuppressive drugs. Today, immunosuppressive drugs and regimens are so effective that many centers report success rates exceeding 90%. Some comments pertinent to the immunology of transplantation will be offered here; detailed consideration will be found in sections devoted to each type of organ transplant and in recent reviews.^{68,80}

5 Immunosuppressive therapy sometimes begins with *induction therapy*. Induction therapy is delivered at the time of transplantation and usually consists of administration of antibodies, such as thymoglobulin, anti-CD3, or anti-CD25, which deplete or block the function of T cells. These treatments decrease the likelihood of early severe cellular rejection. Induction therapy might also limit ischemia-reperfusion injury, to which T cells may contribute. Because induction therapy acts directly and rapidly on many T cells, the treated individual is highly susceptible to infection and to dissemination of viruses and fungi.

The recipients of transplants are always treated with maintenance immunosuppressive therapy. Agents used for maintenance therapy are listed in Table 33.5. Combinations of agents listed in the table are usually employed to limit the complications of the drugs, because the drugs act synergistically, or both.

Given the strength and the quality of alloimmune responses, one might reasonably question why immunosuppression is effective and why the clinical course of those treated effectively is not dominated by infection. Table 33.3 compares features of the alloimmune response with features of the response against

TABLE 33.5

SOME AGENTS USED FOR MAINTENANCE IMMUNOSUPPRESSION

■ CLASS OF AGENT	■ MECHANISM ^a	■ EXAMPLES
Glucocorticoids	Regulate gene transcription	Prednisone
Calcineurin inhibitors	Inhibit protein kinases and phosphatases	Cyclosporine, tacrolimus, rapamycin
Antimetabolites	Inhibit de novo synthesis of nucleic acids	Azathioprine, mycophenolate mofetil, leflunomide

^aThe mechanisms listed predominate for class of immunosuppressive agent; however, immunosuppressive agents often act through several mechanisms, of which only one is listed.

Bacillus Calmette-Guérin (BCG). If the immune response to BCG is weaker and less predictable than the immune response to a transplant, one might predict that the response to BCG should be suppressed at lower doses of immunosuppression than immunity to transplantation. The surprising efficacy of immunosuppression for transplantation might be explained as an example of differential susceptibility of naïve and memory T cells to suppression. Thus, protective immunity conferred by memory T cells is not much abrogated by immunosuppression, and subjects presensitized to a given donor often require more immunosuppression and even then are much more susceptible to severe rejection than naïve recipients.

Immunosuppressive drugs are also used to treat established episodes of rejection. Therapeutic regimens often consist of the anti-T-cell antibodies used for induction and/or higher doses of corticosteroids. The drugs most effective for maintenance immunosuppression, particularly the calcineurin inhibitors, are not effective for treatment of established episodes of rejection. The ineffectiveness of calcineurin inhibitors for treatment of rejection is consistent with the concept that maintenance immunosuppression inhibits differentiation of naïve T cells into effector memory T cells and that cells so differentiated are less susceptible to immunosuppression.

INDUCTION OF TOLERANCE

The induction of tolerance for transplantation has been a central goal of transplantation immunology for five decades.^{81,82} How to accomplish this goal without exerting undue toxicity has been difficult. Two general approaches have been proposed.

One approach to inducing allogeneic tolerance involves elimination of mature lymphocytes and other hematopoietic cells and provision of hematopoietic stem cells of the would-be transplant source, which would potentially rebuild an immune system lacking responsiveness to the hematopoietic cell source. If the source (transplant donor) is fully allogeneic, the approach should fail.⁸³ The thymus of the treated individual would select T cells, the function of which are restricted to the MHC of the treated individual, while the antigen-presenting cells would express incompatible MHC. In practice, however, the approach could work since fully allogeneic human thymus is capable of selecting T cells cross-reactive with allogeneic MHC.⁸⁴ Regardless, the problem of incompatible MHC can be overcome by administering hematopoietic stem cells of both the donor and the recipient.⁸⁵ The main deterrent to applying this approach to tolerance resides in the need to eliminate mature T cells and B cells. In the absence of mature lymphocytes, especially memory cells, the treated individual lacks the ability to protect against infection and the thymus of the mature individual may allow this defect to be repaired only slowly, if at all.

Another approach to inducing tolerance involves administration of inhibitors of costimulation, such as blockers of CD80, CD86, CD40, and CD40 ligand.^{68,86} This approach prevents naïve T cells from being activated but avoids the eradication of memory lymphocytes and hence maintains acquired host defense. However, full tolerance is not induced and in some experimental model systems ongoing treatment is needed. The limitations may prove even more challenging because the approach does not inhibit memory T cells to any great extent and because T cells that protect against some infectious agents such as cytomegalovirus also recognize HLA.

B CELLS IN TRANSPLANTATION

B cells develop in the fetal liver and in the bone marrow of adult mammals from multipotent hematopoietic stem cells. In contrast to T cells, B cells are produced continuously throughout life. The most important feature of B-cell development is the assembly of a functional B-cell receptor, which is a membrane-bound

immunoglobulin. Immunoglobulins are composed of two equal heavy and two equal light chains. Heavy and light chains have two functional domains: the variable region, which confers antigen-binding properties to the immunoglobulin, and the constant region, which confers the functional properties associated with antibodies. Immunoglobulins, like T-cell receptors, differ from most proteins in that their genes are not preformed in the germline. Immunoglobulin (Ig) heavy (H) and light (L) chain variable region exons are encoded by fragmented gene segments, variable (H+L), diversity (H), and joining (H+L) segments that must be joined by a process called *V(D)J recombination*, to generate a functional variable exon. The constant region exons are preformed in the germline. Following rearrangement of the variable gene exon, the IgH locus originates transcripts encoding Ig μ and Ig δ , containing the μ and δ HC constant region exons, which are produced by alternative splicing of a single transcript. The μ and δ heavy chains associate with light chains to produce IgM and IgD, which mark naïve B cells.

Upon activation, B cells secrete antibody as they lose membrane-bound Ig. Secretion of antibody is brought about by engaging an earlier transcription termination sequence, which excludes the membrane-encoding exons from the mature transcript. Activation of B cells also causes somatic hypermutation of the variable region exons and isotype class switch recombination. Somatic hypermutation consists of the introduction of frequent point mutations in the DNA encoding the heavy and light chain variable gene exons. Some mutations inserted in the variable region exons cause amino acid changes that modify the affinity of the antibody to its antigen. Because B cells that bind antigen better have a selective advantage, increased antibody affinity increases the likelihood of survival and favors the development of B-cell memory by creating long-lived quiescent memory B cells and long-lived antibody-secreting cells.

The various IgH isotypes are generated following B-cell activation by recombination between specialized genomic regions upstream of the constant heavy chain exons following class switch recombination. Briefly, isotype class switch consists of replacing the DNA encoding μ and δ constant regions with DNA encoding γ , α , or ϵ constant regions. The exchange is caused by recombination between specialized highly repetitive regions called the *switch regions* located in the intron upstream of the first exon of each constant region, with the exception of δ . Recombination involves loop-out and deletion of the intervening sequences, making class switch recombination an irreversible process. For example, once a cell produces IgG, it can no longer revert to producing IgM from the same allele.

While completely distinct processes, somatic hypermutation and class switch recombination share one necessary initiation factor, an enzyme called the *activation-induced cytidine deaminase* (AID). AID is required for somatic hypermutation and for class switch recombination.⁸⁷ AID deaminates cytidines to form uracyl (U), which is not a normal base in DNA. Introduction of U opposite a G in DNA creates a mismatch, which is resolved by DNA repair components to create point mutations or eventuating in recombination between switch regions.^{88,89} It has been suggested that repair of the U-containing lesion necessarily originates DNA breaks that promote either error-prone repair, causing point mutations, or class switch recombination.^{88–90}

TYPES OF B-CELL RESPONSES

Naïve B cells that come in contact with their cognate antigen differentiate into antibody-producing plasma cells or into memory cells. The path to the plasma cell differs according to the type of antigen. B cells responding to T-independent antigens differentiate into plasma cells without T-cell help but do not generate memory cells. B cells responding to T cell-dependent antigens require T-cell help to differentiate into plasma cells or into memory cells.

Transplants, blood transfusions, and pregnancy evoke humoral responses, the immunizing antigen being the donor blood group antigens, allogeneic MHC, and occasionally other foreign proteins. Blood group antigens are polysaccharides and evoke antibody responses that do not require T-cell help and are therefore called *T cell-independent responses*. Because blood group sugars are inserted onto a protein backbone, B cells that internalize part of the protein that serves as an anchor to the blood group can mount T cell-dependent antibody responses by engaging help of T cells specific to the protein backbone. Thus, T cell-dependent anti-blood group antibody responses require the activation of T cells that are specific to the allogeneic determinants of the protein bound to the blood group. Anti-blood group antibodies are often referred to as “natural” antibodies. The designation “natural” refers to the fact that these antibodies are found prior to exposure to the blood group to which they bind. Because the sugar residues that form the blood groups are abundantly present as part of bacteria walls, it is widely believed that anti-blood group antibodies are evoked in response to commensal bacteria, explaining their universal presence.

T cell-independent (TI) B-cell responses originate through one of two pathways. T cell-independent type 1 (TI-1) responses are initiated by *polyclonal activators*, such as lipopolysaccharide, which stimulate B cells through toll-like receptors.⁹¹ T cell-independent type 2 (TI-2) responses are initiated by polysaccharide antigens and evoke antibodies that are important in the clearance of encapsulated bacteria and enteroviruses. TI-2 antigens have high molecular weight and repetitive epitopes and can thus stimulate B cells through extensive cross-linking of their surface Ig, which probably overcomes the need for T-cell help.

While it is generally accepted that antibody responses to soluble polysaccharides may be evoked in the absence of T-cell help and CD40/CD40L interaction, T cells and CD40/CD40L interaction enhance IgM and IgG antipolysaccharide responses.^{92–96} In contrast, CD8⁺ T cells depress antipolysaccharide responses. How polysaccharides activate T cells is an unresolved question. Because polysaccharides resist degradation *in vivo*, they may persist in the animal, stimulating continuous B-cell activation and long-lived antibody responses.

All allotransplants may potentially evoke anti-MHC T cell-dependent antibodies, the impact of which varies profoundly with the type of transplant. T cell-dependent (TD) responses originate with the activation of T-helper cells and then proceed through the interaction of protein antigens with the B-cell receptor. Activation of B cells in this way depends absolutely on cognate T-cell help. B cells activated by protein antigens in the presence of T-cell help migrate to lymphoid follicles and form germinal centers. Here they are induced by T cells to proliferate, differentiate and hypermutate the variable region of Ig genes, switch Ig class, and give rise to plasma cells and long-lived memory B cells. Because the sequential activation of T cells and B cells in the T cell-dependent response takes time, TD antibody responses generally take much longer than T cell-independent antibody responses and are often too late to clear primary infections. However, because TD antibody responses generate high-affinity antibodies and long-lasting memory, antigens or organisms carrying TD antigens are rapidly and effectively neutralized by the memory responses. In transplantation, B-cell memory responses are one of the most vexing challenges. Memory B cells and long-lived plasma cells are resistant to B cell-depleting strategies, which effectively block antibody production *de novo*.

B-CELL MEMORY

The *raison d'être* of adaptive immunity is immunologic memory, and memory was the first feature of the immune system to be recognized. B-cell memory is characterized by a faster and more effective antibody response following a repeated antigen encounter, and is manifested by heightened clearance

of the antigen. B-cell memory relies on persisting long-lived plasma cells that reside in the bone marrow or *de novo* generation of short-lived plasma-cells from long-lived memory B cells.^{97–99} Long-lived plasma cells may be insufficient to maintain antibody levels because they may not last as long as the individual and because they must compete with newly formed plasma cells for the niches supporting their survival.¹⁰⁰ Thus, long-lasting humoral immunity may depend on the continuous differentiation of plasma cells from memory B cells in response to persisting antigen, to polyclonal stimuli such as nonmethylated CpG DNA acting on the TLR9 receptor, to noncognate T-cell help, or to cross-reactivity with self-antigens, or in response to stimulation by anti-idiotypic antibodies.^{101,102} Whether B-cell memory requires persistence of antigen remains controversial.

B-CELL TOLERANCE

Humoral tolerance defines specific absence of a humoral immune response following an adequate stimulus in an individual fully able to respond to other immune stimuli. This definition has three critical parts. First, *tolerance* refers to the immune response and not its impact. Second, the stimulus must be adequate to induce a perceptible response; all foreign proteins are not immunogenic. Third, nonresponsiveness must be specific for the tolerizing antigen; absence of response in an immunosuppressed or immune-incompetent subject may not reflect tolerance.

Clonal deletion, receptor editing, and anergy establish tolerance in immature B cells or when the autoantigen is present during development. Elimination of self-reactive B cells is called *clonal deletion*. Membrane-bound antigens and complex autoantigens, such as DNA, that possess repetitive epitopes, with the potential to cross-link the B-cell receptor, induce central and/or peripheral deletion of antigen-specific B cells.¹⁰³

Bone marrow B cells may also become self-tolerant by receptor editing. Receptor editing postulates that low-affinity/avidity self-antigen binding on immature B cells induces rearrangements of the immunoglobulin genes changing the cell specificity from self to non-self and presumably rescuing it from death. This salvage mechanism was first postulated to occur in immature B cells in the bone marrow.

Tolerance to soluble autoantigens is achieved by functional inactivation of self-reactive B cells. Anergic B cells express decreased amounts of surface IgM and have decreased responsiveness to B-cell receptor-mediated stimulation and shortened lifespan. Anergic B cells undergo apoptosis induced by Fas.

The mechanisms that establish tolerance of immature B cells are less efficient at precluding antibody production from mature B cells, as well illustrated by the fate of ABO-incompatible cardiac grafts in human subjects. While spontaneous tolerance occurs to A and B blood group antigens in infants with cardiac transplants, the same does not occur later in life. Infants lack the ability to produce antipolysaccharide antibodies including anti-blood group antibodies. Thus, without preexisting antibodies, the newborn becomes tolerant probably through deletion of B cells committed to producing anti-blood group antibodies upon exposure to a graft carrying these antigens. In contrast, adults who receive organ transplants carrying foreign blood group antigens continue to make anti-blood group antibodies because mature B cells are not susceptible to mechanisms that would eradicate or inactivate immature B cells.

IMPACT OF IMMUNITY ON TRANSPLANTS

Why the alloimmune response is more destructive than other immune responses is not fully understood. Alloimmune

FIGURE 33.8. A: The origin of blood vessels in cell, tissue, and organ grafts. Both cell and tissue grafts are fed at least in part by blood vessels of the recipient. Organ grafts depend entirely on blood vessels of the donor. The consequences of this difference are shown in panels B and C. B: Cell and tissue transplants. Fed by blood vessels of the recipient, cell and tissue transplants are susceptible mainly to early nonfunction, perhaps owing to ischemia and cellular rejection. Antibodies and complement of the recipient penetrate poorly through blood vessel walls and hence do not injure these grafts. C: Organ transplants. An organ transplant is fed entirely by vessels of the transplant donor. Consequently, antibodies made by the recipient can bind to the blood vessel walls and cause injury manifest as hyperacute or acute vascular rejection and chronic rejection. Under some circumstances antibodies can cause an organ graft to resist immunological injury. This condition is called accommodation.

responses mainly attack blood vessels.^{29,53,54} The targeted cells rapidly impair blood flow to transplanted organs and tissues. Since all donor blood vessels and many recipient blood vessels are affected, the impact is diffuse and profound and the viability of the transplant is rapidly compromised. As a related consideration, the direct attack of T cells, antibodies, and complement on transplanted cells may preclude the development of accommodation.

- 6 The impact of immunity on transplants depends to the greatest extent on whether transplants consist of cells, tissues, or organs (Fig. 33.8).¹⁰⁴ All transplants are susceptible to cellular rejection. However, transplants differ profoundly in susceptibility to humoral immunity. The differential susceptibility to humoral immunity reflects in large part the way in which the transplant receives its vascular supply.

Isolated cells, such as hepatocytes, derive their vascular supply entirely from the host.¹⁰⁵ Antibodies of the recipient do not bind to blood vessels in these grafts, and very limited amounts of antibody penetrate the vessels to reach the allografted cells. The level of complement outside of vascular lumina is much lower than inside. Hence, blood vessels of the recipient of a cellular transplant shield the transplant from antibody- and complement-mediated injury.

Free tissues, such as skin and pancreatic islets, derive their vascular supply both by the in-growth of blood vessels of the recipient and by spontaneous anastomosis of graft and host capillaries. Antibodies of the recipient can bind to donor segments of these vessels and in doing so may cause focal ischemia in some types of grafts via vascular reactions.^{106,107} Vascularization of tissue grafts by blood vessels of the recipient provides a parallel supply of blood and a partial shield against humoral injury.

Organ grafts such as heart, kidney, liver, and lung derive blood flow from the surgical anastomosis of donor and recipient vessels. The graft is thus fed entirely through a vascular system that is foreign to the immune system of the recipient. Antibodies of the recipient can bind to these foreign vessels. Antibody-mediated injury is observed in organ grafts to a much greater extent than in cell or tissue grafts. Furthermore, because immunoglobulins are largely confined to vascular

spaces, alloreactive antibodies have minimal direct impact on parenchymal cells.^{105,108}

HYPERACUTE REJECTION

Hyperacute rejection occurs within 24 hours of reperfusion and is characterized by immediate loss of graft function and by a pathologic picture of interstitial hemorrhage, thrombosis, and varying extents of inflammation. Hyperacute rejection is thought to be caused by antidonor antibodies binding to blood vessels and activating the complement system in a newly transplanted organ. The development of hyperacute rejection depends absolutely on the activation of complement, and inhibition of complement nearly always prevents hyperacute rejection.⁷³

Anti-HLA antibodies most often cause hyperacute rejection of clinical allografts. Hyperacute rejection occurs in up to 80% of the kidneys transplanted into recipients with cytotoxic antibodies detected by cytotoxic cross match⁷⁸ (Fig. 33.9). Hyperacute rejection is now observed rarely because assays for anti-HLA antibodies identify subjects at risk and transplantation is avoided. FACS methods are especially sensitive but they may also exclude from transplantation recipients with very low levels of anti-HLA antibodies or non-complement-fixing antibodies who might safely receive a transplant.¹⁰⁹ The lymphocytotoxic cross match illustrated in Figure 33.9 is less sensitive, but a positive result may predict hyperacute rejection with more confidence.

Antibodies directed at blood group A and B antigens in a graft can also cause hyperacute rejection. Gleason reported that 46% of ABO-incompatible allografts never gained function and at 12 months only 1 of 24 ABO-incompatible renal transplants continued to function, whereas only 9% of a large group of ABO-compatible grafts did not show early function.¹¹⁰ Whether anti-blood group antibodies cause hyperacute rejection depends on such factors as the antibody levels and the affinity and susceptibility of the graft to injury. For example, the A2 antigen interacts less well with anti-A antibodies; hence, organs expressing A2 transplanted into recipients of blood group O are less susceptible to destruction by humoral responses.¹¹¹

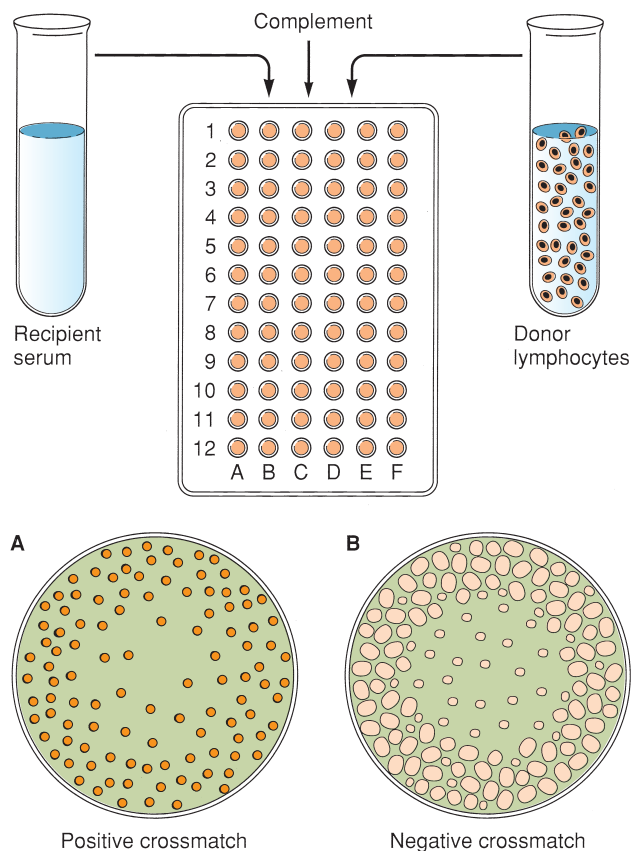

FIGURE 33.9. Lymphocytotoxicity cross match. Recipient serum is incubated with donor lymphocytes and complement in microtiter plates. If donor-specific lymphocytotoxic antibodies are present in the recipient serum, antibody binding results in complement fixation and lysis of the donor lymphocytes. This is detected by the addition of a dye that is taken up through the damaged cell membrane, and a positive cross match is noted (A). If no antibodies are present, cells remain viable and do not take up the dye (B). This is a negative cross match. A more sensitive approach to cross matching involves use of the fluorescence activated cell sorter (FACS) (not shown). This device detects antibody binding with great sensitivity but does not detect whether binding would be injurious.

ABO-incompatible organs vary in susceptibility to hyperacute rejection, liver transplants being less susceptible than kidney or heart transplants. The 3-year graft survival rate for ABO-compatible liver grafts and ABO-incompatible grafts is remarkably similar, 39% and 36%, respectively.¹¹² Differences in the size of the vascular beds may explain the varying susceptibility, as a given amount of antibody and complement would be deposited less densely in the liver than in a smaller organ such as the kidney. The liver also intrinsically resists injury by complement.^{73,113}

Hyperacute rejection sometimes occurs in recipients lacking detectable antidonor antibodies. In some cases, antibody capable of causing rejection is present in the blood but is not detected by assays in which leukocytes are used as the target. For example, the major histocompatibility complex class I-related chain A is not expressed on leukocytes but is expressed on endothelial cells, and antibodies against that antigen have been postulated to cause some cases of hyperacute rejection in recipients with a negative cross match.^{114,115} Similarly, antibodies against yet undefined endothelial antigens have also been linked to rejection of transplants between HLA-identical sibling transplants.¹¹⁶ In other cases, the recipient may truly lack antidonor antibodies and the alternative or lectin pathways without the involvement of antibody may activate complement.

Some antibodies can activate complement through the alternative pathway.^{117,118} Hyperacute rejection can occur independent of antidonor antibodies, and these cases may reflect activation of the alternative or lectin pathways as might occur with ischemic injury.^{119,120} Prolonged preservation and high perfusion pressures in allografts can cause lesions that are pathologically similar to those found in hyperacute rejection.^{121,122}

Prevention and Treatment of Hyperacute Rejection

Hyperacute rejection is prevented by using the cross match to identify recipients at risk and avoiding transplantation when the cross match is positive. In experimental settings, hyperacute rejection is prevented by administration of complement inhibitors. Use of complement inhibitors cannot be justified when alternative recipients are available. Further, experimental studies suggest that if hyperacute rejection is prevented in this way, acute antibody-mediated rejection will ensue. No therapy has proven effective for hyperacute rejection once it has begun.

ANTIBODY-MEDIATED REJECTION

Antibody-mediated rejection is a vexing condition.^{123,124} Previously known as “humoral rejection” and before that as “acute vascular rejection,” antibody-mediated rejection has been considered very difficult and expensive to reverse. Most cases appear to be caused by antibodies and therefore the term *antibody-mediated rejection* is used.

Antidonor antibodies such as those directed at MHC antigens likely trigger antibody-mediated rejection. The timing of antibody-mediated rejection after transplantation depends mainly on when antidonor antibodies are produced. In the absence of immunosuppression, antibody-mediated rejection can begin within 24 hours of transplantation and proceed over days if the recipient is sensitized to donor antigen. In immunosuppressed recipients, antibody-mediated rejection usually appears weeks or months after transplantation.

Evidence of antibody-mediated rejection can be found in 20% to 30% of episodes of acute rejection, but the diagnosis of antibody-mediated rejection is sometimes challenging.¹²⁵ Although antibodies specific for the donor are sometimes found in the circulation, such antibodies are not often found at high levels. The absence of antidonor antibodies does not exclude antibody-mediated rejection, because an organ graft can absorb tremendous amounts of antibody, leaving little or none in the blood.¹²⁶ Also, the antibodies found in the blood may be of lower affinity and thus may not represent the antibodies bound to the graft and those that cause tissue injury.

Because of the limited value of measuring antidonor antibodies, pathologists have turned to the detection of C4d as diagnostic evidence of antibody-mediated rejection.¹²⁷ C4d deposits in peritubular capillaries of transplant recipients with circulating donor-specific antibodies strongly suggest that C4d is a specific and reliable indication of antibody-mediated rejection following kidney transplantation.¹²⁸ Formed by cleavage of C4b covalently bound to target cells, C4d is functionally inert and hence a relatively enduring footprint of complement activation. Since C4 can be cleaved during activation of the classic pathway, the presence of C4d on the endothelium of a graft is taken as evidence that antidonor antibody has bound to that site. C4d is also generated during activation of the lectin pathway; hence, it might be found in some conditions in which antidonor antibodies do not exist. C4d can also be

found in accommodation, a condition in which the graft resists injury caused by antibody and complement. Given these considerations, detection of C4d should not be taken by itself to mark antibody-mediated rejection; other evidence is needed to make that diagnosis.

Antibody-mediated rejection is characterized pathologically by focal ischemia, severe injury to the endothelial cells lining blood vessels in the graft, and intravascular coagulation. Antibody-mediated rejection is thought to be caused by endothelial cell activation in the graft.^{129,130} Normally, resting endothelial cells inhibit coagulation through expression of such anticoagulant molecules as thrombomodulin and heparan sulfate proteoglycan.^{131,132} The binding of antidonor antibodies to endothelium in the graft and the activation of complement disrupt the quiescent state and cause the endothelium to become activated. Activated endothelial cells promote coagulation by shedding thrombomodulin and heparan sulfate proteoglycan and subsequently expressing tissue factor and plasminogen activator inhibitor type 1.¹³³ Inflammation is promoted by activated endothelial cells, which induce expression of cell adhesion molecules and cytokines.¹³⁴ Complement-induced coagulation and inflammation both appear to be governed by transcription and production of IL-1 α and by the availability of that cytokine to act in local blood vessels.^{135,136} Coagulation and inflammation impair the flow of blood through regions of the vasculature, and this impairment probably accounts for the pathologic manifestations of antibody-mediated rejection, which are most consistent with ischemia.

Prevention and Treatment of Antibody-mediated Rejection

For many years, antibody-mediated rejection was thought to be inseparable from cellular rejection, but unlike cellular rejection, it resisted all therapeutic efforts. Recently, better approaches to treatment have emerged. Plasmapheresis, sometimes used in conjunction with administration of cytotoxic drugs, can effectively overcome established episodes of antibody-mediated rejection. This therapy engenders risk and is quite expensive. Administration of γ -globulin, sometimes in conjunction with plasmapheresis, has also proven effective. Gamma-globulin inhibits production of antibodies, blocks Fc receptors, and diverts activated fragments of complement away from endothelium. Anti-B cell antibodies, such as anti-CD20, have been used in some cases of antibody-mediated rejection with anecdotal claims of success. If confirmed, the success of these antibodies might point to functions of B cells other than antibody production, since plasma cells, which do not express CD20, probably produce most alloreactive antibodies.

CHRONIC REJECTION

- 8 Chronic rejection, more than any other condition, limits the long-term success of solid organ transplantation. Chronic rejection or chronic graft dysfunction may be caused by a number of processes, particularly repeated inflammation and injury from both immune- and non-immune-mediated causes. In the kidney, chronic rejection is sometimes called *chronic allograft nephropathy*; in the heart, *accelerated arteriosclerosis*; in the lung, *bronchiolitis obliterans*; and in the liver, *vanishing bile duct syndrome*. The term *chronic rejection* might best be applied to chronic graft dysfunction caused by an immunologic reaction and chronic allograft dysfunction caused by drug toxicity, ischemia, aging, and other nonimmunologic processes. While the clinical signs are organ specific, the result of chronic rejection is similar for all solid organ allografts - inexorable loss of function. Obliterative vasculopathy, infiltration of leukocytes, luminal occlusion, and a marked fibrotic response are common to many

types of chronic rejection and are believed to account for loss of function.

Antidonor antibodies cause up to 60% of chronic dysfunction of organ transplants.¹³⁷ Circulating antidonor HLA antibodies correlate strongly with chronic rejection.¹³⁸ De novo anti-HLA antibodies are always present prior to graft failure. Whether antidonor antibodies actually cause chronic rejection or reflect a response to a damaged graft caused by other factors has not been determined.

The presence of C4d deposits seen in chronic graft dysfunction has been taken to implicate humoral immunity in the loss of graft function; 64% of subjects with chronic rejection have C4d deposits in graft biopsies.¹³⁹ In one report, all with donor-specific antibodies at the time of biopsy also had C4d deposits, and 90% of those positive for C4d also had antidonor antibodies.¹³⁷ C4d deposits precede and predict the development of chronic allograft glomerulopathy.¹⁴⁰ No treatment has proven effective for chronic rejection.

ACCOMMODATION

Accommodation refers to acquired resistance of an organ graft to humoral injury. Accommodation was first described and later named based on observations of the outcome of ABO-incompatible kidney transplants.^{72,73,141} In the mid-1980s, several investigators observed that if anti-blood group antibodies were removed from the circulation at the time of transplantation, kidneys transplanted across blood group A or blood group B barriers could survive and function.^{70,71} This suggested that incompatibility of blood groups was not an absolute barrier to transplantation and prompted the question of how these kidneys survived. Some recipients had antibodies specific for donor blood groups and the transplanted kidneys continued to express donor antigen, but graft injury and compromise of function did not occur. This observation suggested that the survival of the graft must reflect some change in the graft itself. Accommodation may be more frequent than currently assumed.¹⁴² Healthy organs can absorb antidonor antibodies in large amounts, removing these antibodies from the circulation, and hence more recipients may make antidonor antibodies than surveys of the prevalence of antibodies would suggest.

Accommodation might reflect a change in the properties of the antibody or the antigen. Both of these mechanisms have been observed in experimental models. Under some conditions, the Ig subclass of antidonor antibodies does not efficiently fix complement and may even block the binding of complement-fixing antibodies.^{142,143} In other conditions, carbohydrate antigen may be shed or undergo biochemical change and therefore might be less avidly bound.¹⁴⁴⁻¹⁴⁶

While these models may apply in some cases, most studies suggest that accommodation reflects resistance to injury. Exposure of an organ to heme induces heme oxygenase, which can protect the organ against lethal injury by various toxins.¹⁴⁷ Xenografts and allografts with accommodation express a number of "protective," antiapoptotic genes.^{148,149} Products of these genes may prevent cells of the graft from undergoing apoptosis that otherwise would be triggered by humoral immunity. Consistent with this concept, exposure to xenoreactive antibodies induces expression of antiapoptotic genes in endothelial cells.¹⁵⁰ Anti-HLA antibodies likewise induce such genes.¹⁵¹ Further understanding of how accommodation is induced and by what mechanisms it is manifest and maintained could have a profound impact on transplantation in general and perhaps on other fields.

CELLULAR REJECTION

All allografts are subject to cellular rejection, and the clinical application of transplantation depends absolutely on suppressing

or eradicating cellular immune responses to the transplant source. Accordingly, no subject in transplantation has been studied more thoroughly than cellular rejection. Most research has focused on the mechanisms by which T cells are activated and the antigenic target of activated T cells. Much less has been elucidated about how cellular immunity, once induced, destroys transplants and why such destruction is more violent and complete than the tissue injury seen in autoimmune diseases.

Cellular rejection is directed against small blood vessels of the graft, at least initially. The blood vessels appear to be targeted by two fundamental mechanisms.^{152,153} One mechanism involves the action of cytotoxic T cells. The importance of cytotoxic T cells is suggested by the observation that in grafts consisting of mixtures of allogeneic and isogeneic cells, the allogeneic cells are destroyed and the isogeneic cells are spared.¹⁵⁴ In grafts consisting of both allogeneic and syngeneic islets of Langerhans, the allogeneic islets were destroyed, while syngeneic islets, even those adjacent to allogeneic islets, survived.¹⁵⁵ However, early in the course, rejecting allografts do not contain many dead cells. This inconsistency raises the possibility that some function of cytotoxic cells other than killing may account for tissue injury. One potential effector is perforin, a pore-forming protein. Perforin and other pore-forming proteins activate endothelial cells and in so doing could evoke focal ischemia, inflammation, and thrombosis.¹⁵⁶ One concern about implicating cytotoxic T cells in the pathogenesis of cellular rejection is the observation repeated in many laboratories that rejection of allografts can be brought about by helper cells alone and proceeds fully when cytotoxic cells are eliminated.¹⁵⁷ These observations can be explained by the extraordinary extent to which immunity is aroused by allotransplantation; far more effector cells are activated than are needed for rejection.

The second mechanism of tissue injury in cellular rejection can be likened to delayed-type hypersensitivity. Helper T cells and some cytotoxic T cells secrete cytokines that modify the functions of blood vessels to promote leukocyte migration, thrombosis, and ischemia. Cellular rejection departs from delayed-type hypersensitivity in several respects. First, cellular rejection is often dominated by cytotoxic cells (CD8+) and delayed-type hypersensitivity by helper cells (CD4+).^{158,159} Cellular rejection is associated with microvascular injury and thrombosis, whereas delayed-type hypersensitivity is characterized by edema and relatively uninjured blood vessels. Both allograft rejection and delayed-type hypersensitivity may be driven by products secreted by T cells, although the products may differ. Alloreactive T cells may preferentially secrete cytokines and other agonists when the TCR is stimulated by an adjacent allogeneic cell—the same mechanism that ensures specificity of cytotoxic cells for their targets may ensure specificity of helper cells for theirs.

CONCLUDING REMARKS

This chapter reviews the immunology of transplantation as it is practiced in the first decade of the 21st century and elucidated over the past century. However, the practice of transplantation may soon change, as transplants consisting of stem cells, stem cell derivatives, and engineered tissues are used. Stem cells interact with the immune system in ways, very different from mature cells and organs. These differences will become important as surgeons turn increasingly to regenerative medicine and novel approaches to organ replacement for the treatment of disease.

CHAPTER 34 ■ ORGAN PRESERVATION

ROBERT M. MERION

KEY POINTS

- 1 Much of the injury to transplanted organs occurs not during the period of ischemia but during organ reperfusion.
- 2 The general attributes of an acceptable organ donor include pronouncement of donor death, previously good general health, and relative hemodynamic stability from the time of the precipitating event leading to death until organ procurement is complete.
- 3 The following requirements must be met to make a firm diagnosis of brain death: the presence of reversible causes of coma should be excluded; clinical criteria
- 4 All transplant candidates within the United States are entered into a computer system, and an allocation system is used to determine the appropriate potential recipient for a given donor organ.

PATHOPHYSIOLOGY OF ORGAN PRESERVATION INJURY

The removal, storage, and transplantation of a solid organ from a donor results in profound alterations in homeostatic control of the *milieu interieur* of that organ. These effects manifest themselves in the degree to which the return of normal organ function is delayed or prevented once the recipient transplantation procedure is completed. The injury sustained by an organ during the processes of procurement, preservation, and transplantation occurs primarily as a result of ischemia and hypothermia, the former being customarily classified as warm or cold ischemia. Warm ischemia and its consequences are associated with normothermic events that occur before removal of the organ from the body. Cold ischemia refers to events occurring during the interval between initial organ cooling and revascularization in the recipient.

The principles of modern organ preservation are to provide for hypothermia, prevent cellular swelling, and avoid biochemical injury.^{1,2} These principles are intended to interfere with the loss of cellular integrity, changes in ionic composition, and disruption of cellular energy systems that occur during organ storage. The following discussion describes these phenomena. Finally, the effects of oxygen-derived free radicals, cytokines, and nitric oxide at the time of reperfusion are discussed.

Structural Integrity

The cell membrane plays a crucial physical protective role and provides an active interface with the extracellular environment. Receptors, ion regulation, and enzyme systems linked to the cell membrane complex contain extracellular, transmembrane, and intracellular components essential to their function. The interrelation of such systems with the membrane itself is highly dependent on a stable configuration of the lipid bilayer and on tight control of temperature, pH, and osmolality. Organ ischemia and preservation disrupt all these relations. Lowering the temperature through the phase transition of lipids results in profound changes in conformation and stability of the membrane in addition to drastically altering the

function of membrane-bound enzymes. Physicochemical membrane changes induced by hypothermia result in increased permeability, which in turn adds to the burden of maintaining a stable intracellular environment and contributes to cell swelling. Organ preservation solutions have historically therefore been hypertonic to minimize these alterations.

Ionic Composition

The foregoing membrane changes are compounded by crippling of the $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase (ATPase) pump caused by the lack of ATP production and by generation of excess hydrogen ion resulting from anaerobic metabolism during ischemia. When the $\text{Na}^+\text{-K}^+$ -ATPase pump is paralyzed, potassium diffuses down its concentration gradient to the extracellular environment while sodium, normally present at a low concentration in the cell, pours in. Modern preservation solutions have typically had electrolyte compositions similar to that inside the cell with high potassium and low sodium concentrations. Osmotic gradients are, therefore, minimized, and the cellular ionic charge remains relatively constant.

Hydrogen ion production continues in ischemic organs and may result in cellular damage. Intracellular pH gradually falls without replenishment of buffering capabilities, and under conditions requiring a switch from aerobic to anaerobic glycolysis, the production of lactic acid also increases. The liver appears to be especially susceptible to this type of injury. A plausible mechanism has been described whereby glucokinase in the liver phosphorylates glucose (endogenous or provided in preservation solution) to glucose-6-phosphate.³ The normal metabolic pathway for glucose-6-phosphate results in production of pyruvate and ultimately lactate by lactic dehydrogenase (Fig. 34.1). Unlike the kidney, the hepatic isozyme of lactic dehydrogenase, M4, functions particularly well under acidotic conditions in the presence of high concentrations of lactic acid. These biochemical differences underlie the range of acceptable cold ischemia time for various organs.

Calcium ion permeability is increased with ischemia, and a rapid influx of calcium may overwhelm mitochondrial buffering capacity. There is increased activity of calmodulin, a cytoplasmic calcium-binding protein, and a cascade of enzyme activation events, including the upregulation of

FIGURE 34.1. The effects of acidosis on glucose metabolism are organ specific. For example, the M4 isozyme of lactate dehydrogenase (LDH) functions well in an acidotic environment in the presence of high concentrations of lactic acid. G6P, glucose-6-phosphate. (Adapted with permission from Belzer FO, Southard JH. Principles of solid-organ preservation by cold storage. *Transplantation* 1988;45:673–676.)

phospholipases and subsequent production of prostaglandin derivatives, results in mitochondrial and cell membrane injury. Vascular smooth muscle myofibrillar contraction may be initiated by increased cellular calcium concentrations, with the resulting vasospasm contributing to ischemic damage. Endothelin, a 21-amino-acid peptide with potent vasoconstrictor properties, has been recognized as another factor that plays a role in preservation injury by inducing vasospasm after revascularization.^{4,5}

Cellular Energy

The energy requirements of aerobic cells are provided by a combination of the enzymatic breakdown of glucose (glycolysis) and by the process of cellular respiration, encompassing the transfer of electrons from organic molecules to molecular oxygen (electron transport and oxidative phosphorylation) (Fig. 34.2). Hypothermia results in decreased metabolic rate and slows the rate at which enzymes degrade cellular components, but metabolism is not completely suppressed. It has been calculated that cooling from 37°C to 0°C results in a 12-fold reduction of cellular metabolism.¹ Although metabolism is slowed and utilization of cellular energy stores is slowed, ATP and adenosine diphosphate (ADP), the major sources of cellular metabolic energy, are gradually depleted during hypothermia. This depletion is presumably a result of residual energy requirements that exceed the capacity of the cell to produce ATP.

During ischemia and organ preservation, the glycolytic pathway is sidetracked to lactate production as the Krebs tricarboxylic acid cycle and mitochondrial respiration are

impaired. Although some of the enzymes of the Krebs cycle may be found in the extramitochondrial cytoplasm, the inner compartment of the mitochondrion is where the enzymatic reactions of the cycle occur. Mitochondrial dysfunction, therefore, is responsible for most of the changes in cellular energy associated with ischemia and organ preservation.

Hypothermic preservation results in reduced activity of mitochondrial enzymes. Cellular respiration, which requires adenine nucleotide substrates, is reduced. For ADP to be transported into the mitochondrion as a substrate for conversion to high-energy ATP, a membrane adenine nucleotide translocase is required. Hypothermia unfavorably alters the relation between the enzyme and the inner mitochondrial membrane within which it resides, reducing substrate delivery.⁶ Phospholipid hydrolysis by phospholipases increases levels of free fatty acids, acyl derivatives of which may also affect membrane structure and the function of the translocase. Cannibalization of ADP sequestered in the extramitochondrial cytoplasm by adenylate kinase for conversion to ATP results in accumulation of adenosine monophosphate as a byproduct, which reduces purine synthesis and results in the loss of ATP precursors from the cell.

Reperfusion Injury

- 1 It is apparent that much of the injury to transplanted organs occurs not during the period of ischemia per se but upon organ reperfusion. This realization has led to many advances in organ preservation. Furthermore, some of the events that occur during reperfusion may result in enhanced

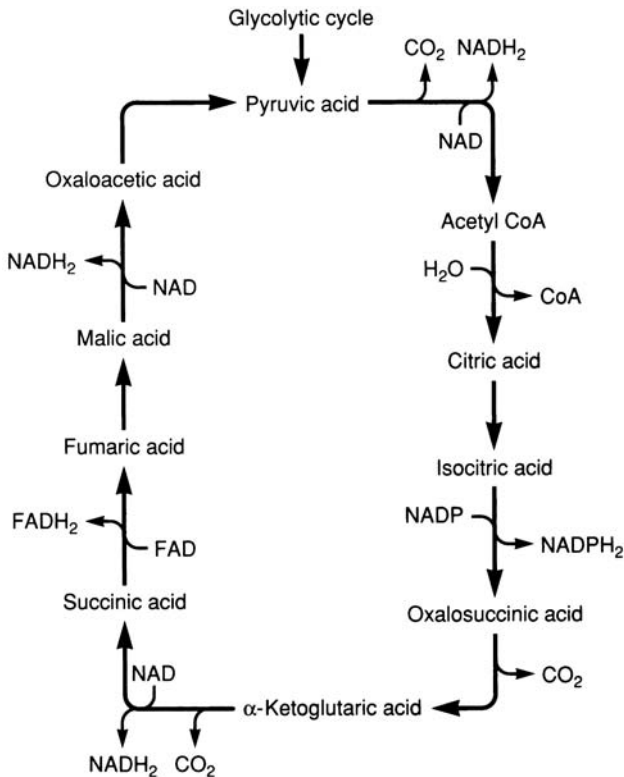

FIGURE 34.2. Cellular energy requirements are met largely through the processes of glycolysis, the Krebs tricarboxylic acid cycle, and oxidative phosphorylation. CoA, coenzyme A; NADH₂, reduced form of nicotinamide adenine dinucleotide; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide-adenine dinucleotide phosphate; NADPH₂, reduced form of NADPH; FAD, flavin adenine dinucleotide; FADH₂, reduced form of FAD.

immunogenicity of the graft. A better understanding of these events will hopefully lead to the development of preservation methods that decrease the propensity for allograft rejection at a later date.

Oxygen Free Radical-mediated Effects

The mechanisms by which reactive species of oxygen are produced in biologic systems and the effects of these molecules on various cells and tissues were elucidated in the 1970s and 1980s.⁷ The best-studied model involves the production of superoxide anion (O_2^-) as a byproduct of the enzymatic catabolism of the purine metabolites hypoxanthine and xanthine to uric acid by xanthine oxidase (Fig. 34.3). During ischemic states, a cytosolic enzyme is activated by increased intracellular calcium, resulting in the conversion of xanthine dehydrogenase to xanthine oxidase. Both xanthine dehydrogenase and xanthine oxidase catabolize hypoxanthine and xanthine to uric acid. Xanthine oxidase utilizes molecular oxygen as an electron acceptor and forms (O_2^-) as a result. Superoxide anion rapidly reacts with itself to form hydrogen peroxide, a potent oxidant capable of injuring the cell by oxidizing lipid membranes and cellular proteins. Hydrogen peroxide then produces a cascade of oxygen free radicals, including hydroxyl radical (OH^\bullet) and singlet oxygen, that are even more potent oxidants. The damaging effects of oxygen free radicals begin upon reperfusion of the organ. During ischemic conditions, tissue oxygen levels fall below the threshold needed to allow xanthine oxidase to metabolize xanthine and hypoxanthine.

FIGURE 34.3. The classic pathway of superoxide anion generation by the metabolism of purines by xanthine oxidase. ATP, adenosine triphosphate; AMP, adenosine monophosphate; Ca^{2+} , calcium; O_2 , oxygen; O_2^- , superoxide anion.

This allows the intracellular concentration of these metabolites to rise. Upon reperfusion, oxygen is suddenly available and metabolism proceeds rapidly, resulting in a dramatic and sudden production of reactive oxygen intermediates. The cellular defenses against peroxidation are overwhelmed and injury occurs.⁸

Agents that reduce oxygen free radical generation, or scavenge them once they are formed, have been used to determine the contribution of these molecular species to preservation-related reperfusion injury and have the ability to decrease peroxidation due to oxygen free radicals during reperfusion. Allopurinol, an inhibitor of xanthine oxidase, has been shown to have protective effects when used before the ischemic insult in a variety of experimental systems. Unfortunately, allopurinol has other effects, such as vasodilatation and preservation of the purine nucleotide pool, making it a less-than-ideal agent for defining oxygen free radical effects. Other studies using superoxide dismutase have clearly demonstrated a role for oxygen radicals in reperfusion injury in transplantation.⁹ Similarly, desferrioxamine, an iron chelator, removes an essential metal cofactor for the generation of the extremely reactive hydroxyl radical, resulting in decreased oxidative injury.

Indirect evidence of oxygen free radical effects rests on the documentation of lipid peroxidation. In this process, interaction of highly reactive oxygen species with polyunsaturated fatty acids in the cell membrane starts a chain reaction that may ultimately destroy cellular integrity and result in cell death. The products of this reaction can be measured by several different assays. The magnitude of lipid peroxidation appears to be inversely related to levels of glutathione, which functions as an endogenous free radical scavenger. Glutathione and other agents that protect against peroxidation are, therefore, useful in organ preservation solutions to attenuate reperfusion injury.

Production of oxygen free radicals also initiates production of prostaglandins including leukotriene B₄ by direct activation of phospholipase A₂. This chemoattractant causes leukocyte adherence to vascular endothelium. These neutrophils may contribute to local injury by plugging the microcirculation and by degranulation, resulting in proteolytic damage to the organ.

Cytokine-mediated Effects

Cytokines are a recently described group of intercellular messenger molecules that may be produced in a variety of normal

and pathophysiologic states. Ischemia and reperfusion are known to be associated with marked release of tumor necrosis factor- α , a cytokine with profound systemic effects.¹⁰ Other cytokines, including interferon- γ , interleukin-1, and interleukin-8 (neutrophil chemotactic factor), may also be released during organ reperfusion and cause upregulation of adhesion molecule expression on vascular endothelium. These changes may lead to leukocyte adherence and platelet plugging following revascularization, resulting in graft failure and an increased risk of later rejection.

Nitric Oxide-mediated Effects

Nitric oxide (NO) is an extremely labile autocoid generated by nitric oxide synthase from L-arginine. It has potent vasodilatory effects on microvasculature and is responsible for a wide variety of physiologic effects. Evidence suggests that NO production is induced by inflammatory cytokines including tumor necrosis factor- α , interferon- γ , and interleukin-1. In the setting of ischemia-reperfusion, NO may, therefore, mediate injury to organs directly as a result of cytokine release. Inhaled nitric oxide has been demonstrated to attenuate reperfusion injury in transplanted lungs.¹¹ Increased NO synthesis also correlates with acute rejection.¹²

CONTEMPORARY CLINICAL PRACTICE

The science of transplantation has developed rapidly during the past 40 years. Improved understanding of the immune response to allografts and better appreciation of the complexity of organ ischemia and preservation-related injury have contributed to greatly improved graft and patient survival results. Most solid organ transplants are now performed as the therapeutic option of choice, and in many cases transplantation offers the only definitive treatment for a given disease entity. As a result, an ever-widening list of indications for solid organ transplantation has emerged, placing increasing pressure on an already limited supply of donor organs. As of December 2006, there were 93,820 patients awaiting deceased donor organ transplantation in the United States, almost double the number listed in 1997.¹³ Each year, more patients are placed on the waiting lists than are transplanted, resulting in thousands of waiting list deaths and increasing waiting time.

Determination of Suitability for Deceased Donor Organ Donation

- 2 **General Considerations.** The characteristics of a suitable deceased organ donor can be divided into those that are general in nature and those that are organ specific. Broadly stated, the general attributes of an acceptable organ donor include pronouncement of donor death, previously good general health, and relative hemodynamic stability from the time of the precipitating event leading to death until organ procurement is complete. Informed consent from the donor's next of kin is required before organ procurement. The concepts of brain death and the renewed practice of donation after cardiac death (DCD) are discussed in detail later. A detailed understanding of these conditions and their associated pathophysiology is essential for the successful procurement and subsequent transplantation of solid organs from deceased donors. A detailed medical history should be sought by contacting family members or friends of the potential donor.

Age. As experience has been gained with donors considered less than ideal, it has become apparent that arbitrarily defined

chronologic age limits for organ donors are unnecessary. Ample evidence supports the relaxation of upper age limits for most abdominal organs. For example, kidney procurement from deceased donors older than age 65 years is routinely considered, and successful renal transplantation has been reported from a deceased donor aged 84 years.¹⁴ Donor age has been similarly de-emphasized in liver transplantation, where more than one third of deceased donors are older than 50. The acceptable upper donor age limit for cardiac transplantation has been cautiously increased, and approximately 8% of heart donors are older than 50.

Transplantation of organs from donors at the younger extreme of life is similarly successful. Some controversy exists with regard to the advisability of transplanting kidneys from infants and children younger than 5 years.^{13,15} Lower graft survival rates have been reported when kidneys from very young donors have been transplanted.¹³ However, individual center and national registry-based analyses show that results using en bloc transplantation of both kidneys from pediatric donors to adults are comparable to those achieved with adult donor kidneys.^{16,17} Other than the kidney, size considerations dictate use of organs from younger, smaller donors for younger, smaller candidates. An important exception is the liver, where lobar transplantation is possible.

Overall Premorbid Health. Because most deceased organ donors have acute cerebral trauma or intracerebral catastrophe as the cause of death, serious associated systemic diseases are relatively uncommon in this population. As the donor population ages, however, the effects of hypertension, atherosclerosis, and other diseases associated with advancing age are more common. Thus, careful screening to ascertain that the donor was previously in good health is mandatory. Common disorders, such as hypertension and diabetes mellitus, do not automatically disqualify a person from organ donation, but the duration, severity, and treatment of such conditions should be evaluated for their potential effects on individual organs.

Hemodynamic Stability. Cardiovascular instability and eventual cardiopulmonary collapse eventually occur in all brain-dead patients. Thus, hemodynamic management is one of the most important aspects of donor management once brain death has been established and consent for organ donation has been obtained. Many potential organ donors sustain significant hypotension or even cardiac arrest during the initial stages of their illness or as the presenting signs of intracerebral catastrophe. Knowledge of the course and management of these episodes is helpful in predicting damage to the various organs and in guiding the workup of the donor for suitability of the organs for transplantation. In terms of specific organs, the kidneys appear to tolerate transient hypotension best, whereas the liver and pancreas may be more severely damaged by such episodes. The cardiac response to hypotension or actual cardiac arrest depends on the cause of the hemodynamic instability and the magnitude of direct cardiac injury sustained as a result of cardiac compressions during cardiopulmonary resuscitation.

Contraindications

Sepsis. Active systemic infection has traditionally been an absolute contraindication to organ donation. However, these tenets are being re-examined because of the current organ shortage. A history of diseases such as tuberculosis or human immunodeficiency virus (HIV) infection clearly renders a person unsuitable for donation. Pneumonia (except for lung donors) and urinary tract infection are no longer considered to be problematic in the absence of systemic sepsis. Even in the presence of bacteremia, the risk of transmission of infectious agents by organ transplantation appears to be small.¹⁸ In all cases, appropriate antibiotic therapy should be initiated before the procurement procedure.

Viral Infection. All potential organ donors, regardless of whether they are considered high risk, are tested for evidence of infection with HIV. Although the incidence of false-positive results may be a problem, the high sensitivity of the test ensures that the potential for transmission of this virus is minimized. Nucleic acid testing for HIV is increasingly available by organ procurement organizations, which further reduces the so-called window period for false-negative test results. Screening for human T-lymphotropic virus (HTLV-1 and HTLV-2) has been done routinely for deceased donors, but concerns about false-positive rates, which result in otherwise suitable organs being discarded, and the recently announced removal from the market of the most commonly used U.S. Food and Drug Administration (FDA)-approved assay, have complicated decision making about testing for this virus. Testing is also routinely performed for evidence of hepatitis B and C virus infection. History of viral hepatitis or serologic evidence of past infection has previously been considered an absolute contraindication to organ donation. Many centers are now reconsidering this issue in selected situations. Some organs from donors who have evidence of past infection with the hepatitis B virus are able to transmit the virus. However, these organs may be considered for recipients who have long-standing infection with this virus or have received the recombinant hepatitis B vaccine and have serologic immunity. In addition, in medically appropriate circumstances, organs may be used from donors who test positive for hepatitis B core antibody and negative for hepatitis B surface antigen. In such cases, recipients are generally treated with lamivudine or other similar antiviral agents. Organs from donors with evidence of past infection with the hepatitis C virus are possible sources of infectious virus. The risk of infection is small, however, and these organs are now being considered for patients with known preexisting exposure to the hepatitis C virus.¹⁹ Other viral titers that are frequently determined during workup of a donor include members of the herpesvirus family, such as cytomegalovirus (CMV), Epstein-Barr virus, and herpes simplex virus. Evidence of previous infection with these viruses does not preclude organ donation but may require additional therapy in the recipient, such as valganciclovir prophylaxis or hyperimmune globulin administration in the case of CMV.

Cancer. Cancer, whether treated or not, has long been considered to contravene organ donation based on the knowledge that tumor cells may circulate widely even in patients with malignant lesions thought to be localized. The transplantation of even a small number of malignant cells into a recipient who is heavily immunosuppressed carries the threat of dissemination and a disastrous outcome. The only exception to this rule has been the donor with a primary malignancy of the central nervous system. It has long been thought that as long as the blood-brain barrier is intact, these tumors are rarely capable of systemic spread. Although transmission of central nervous system tumors of donor origin to transplant recipients has been reported, the rate of transmission is dependent on the organ transplanted and the type of malignancy involved.²⁰ These cases must be considered on an individual basis.

Specific Organ Dysfunction. The condition of particular organs of interest in great measure dictates their individual suitability for transplantation. With appropriate emphasis on the overall maintenance of donor homeostasis, most if not all transplantable organs should be procured from most donors. A history of longstanding hypertension may result in fixed damage to the kidneys as a result of hypertensive scarring and secondary to the effects of aortic and renal atherosclerosis. Similarly, insulin-dependent diabetes mellitus produces a well-known renal lesion. These changes may be reversible, however, after transplantation into a nondiabetic recipient.²¹ The kidneys are relatively resilient organs, and simple measures usually suffice to identify serious renal dysfunction. Measure-

ments of hourly urinary output, coupled with determinations of the central venous pressure, are useful monitors of the adequacy of volume repletion in potential donors. Significant volume depletion is the combined result of intentional volume contraction to treat cerebral edema and the effects of diabetes insipidus accompanying lethal brain injury. Serum creatinine is measured as a global, if imperfect, indicator of renal function. Significant elevation of the serum creatinine level during the course of the donor hospitalization may be a sign of renal injury, predisposing to delayed graft function after transplantation, although eventual outcomes may be very acceptable in the face of acute tubular necrosis in young and otherwise uncomplicated donors.^{22,23}

Preexisting liver disease usually can be identified before organ procurement. A history of cirrhosis precludes donation. Prior cholecystectomy for uncomplicated cholelithiasis is not a contraindication to liver donation. Standard liver function tests, such as serum alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and bilirubin, may be helpful in identifying gross injury to the donor liver resulting from traumatic, metabolic, or hemodynamic causes, but the absolute levels of these tests are poor indicators of the likelihood of immediate, life-sustaining graft function in the recipient. Hepatic synthetic function as assessed by prothrombin time may also be deceiving because of the effects of severe brain injury on the coagulation cascade.²⁴ An increasing incidence of obesity has led to higher rates of nonrecovery and discard of donor livers due to steatosis. Bedside donor liver biopsy is increasingly utilized to avoid the high cost of unnecessarily dispatching procurement teams to donor hospitals.

The pancreas may be difficult to assess until the time of organ procurement. Hyperglycemia and hyperamylasemia are common in patients who sustain brain death, particularly if the cause is traumatic. A careful history establishing the absence of preexisting diabetes mellitus and pancreatitis provides the most useful information. A history of alcohol abuse alone does not correlate well with the finding of chronic pancreatitis pathology at laparotomy. Computed tomographic examination of the abdomen may be indicated if the donor sustained any abdominal injury. It is more appropriate to examine the organ at the time of multiple organ procurement to determine if it is suitable for transplantation rather than making a decision on the basis of historical or laboratory information alone.

Intestinal donation still occurs quite uncommonly. Fewer than 200 candidates are on the waiting list in the United States at any given time, and many of these are children for whom appropriate size matching is required.

Cardiac dysfunction resulting in arrhythmia or the need for high-dose inotropic support suggests that the heart may be unsuitable for transplantation. Transient supraventricular tachycardias, ventricular arrhythmia associated with severe hemodynamic instability, or cardiac arrest requires investigation before acceptance as a cardiac donor. Significant valvular disease and wall motion abnormalities can be readily identified by bedside echocardiographic examination, a study that is routinely obtained by many transplant centers. In many cases the fluid management of the donor radically affects the apparent cardiac function since over- or underhydration will markedly reduce effective cardiac output. Urine output can be extremely misleading due to the loss of antidiuretic hormone secretion from the hypothalamus. Measurements of central venous pressure or pulmonary artery wedge pressure may allow for more accurate management of fluid replacement. Determination of cardiac output using a flow-directed balloon-tipped pulmonary artery catheter is also helpful and complements echocardiographic findings. In questionable cases, cardiac catheterization may be required to exclude significant coronary artery disease.

Pulmonary donation is dependent upon satisfactory gas exchange parameters and an absence of major lung disease

history. In the setting of conditions that lead to deceased organ donation, oxygen saturation and arterial oxygen tension (PaO_2) may be suboptimal. However, lung resuscitation protocols have resulted in greater likelihood of successful placement of donor lungs for transplant.

Brain Death

3 Definition. The concept of brain death was crystallized in the 1968 Report of the Ad Hoc Committee of Harvard Medical School developed to examine the definition of brain death.²⁵ This document established the following clearly defined criteria that were reliably predictive of irreversibility: (a) unresponsivity and unresponsivity, (b) absence of spontaneous muscular movement, (c) absence of reflexes, and (d) silent electroencephalogram. Since the publication of the so-called Harvard Criteria, the prerequisites for the diagnosis of brain death have been refined. Most hospitals have constituted a Brain Death Committee that is responsible for making uniform determinations of brain death according to locally established specific criteria while conforming generally to the Harvard Criteria. The following requirements must be met to make a firm diagnosis of brain death: (a) the presence of reversible causes of coma should be excluded, (b) clinical criteria establishing the loss of all functions of the entire brain must be met (deep coma, absence of brainstem function, absence of spontaneous respiration), and (c) a confirmatory diagnostic test must be carried out (electroencephalogram, nuclear brain blood flow study, four-vessel cerebral arteriography).

Reversible causes of coma include sedation, hypothermia below 32.2°C , neuromuscular blockade, and shock. Coma should be deep and fixed, without perception or response to external stimuli, including deep pain. Decerebrate and decorticate responses should not be present. Occasionally, spinal reflexes may be present. Absence of brainstem function can be documented by confirming the absence of pupillary light response, corneal reflex, oculocephalic reflex, oculovestibular reflex, and spontaneous respiration.

An apnea test should be performed to assess spontaneous respiration. Ventilation of the patient with 100% oxygen for 10 minutes before the test reduces the risk of hypoxemia and subsequent cardiovascular collapse. After the period of preoxygenation, passive flow of oxygen into the endotracheal tube is continued, and the patient is monitored for evidence of respiratory effort. During this interval, hypercarbia with an arterial carbon dioxide tension (PaCO_2) greater than 60 mm Hg should be documented by arterial blood gas testing.

The confirmatory test of choice is an electroencephalogram documenting electrocerebral silence or absence of brain blood flow by nuclear scintigraphy. The electroencephalogram may be done 6 hours after the initial clinical determination of brain death and, when accompanied by a second clinical determination, is diagnostic of brain death. Nuclear scintigraphic determination of brain blood flow is a satisfactory method to provide definitive confirmation of brain death. This test has the advantage that it can be done as a portable examination at the patient's bedside in the intensive care unit (ICU) or emergency department, avoiding the risk of unnecessarily transporting a potentially unstable patient. Alternatively, four-vessel cerebral arteriography demonstrating cessation of blood flow to the brain may be used within an hour of the clinical brain death declaration.

Etiology. Any condition that results in an overwhelming cerebral insult may be sufficient to cause brain death. In general, these conditions fall into the broad categories of subarachnoid or intracerebral hemorrhage, direct cerebral trauma, primary malignancy of the central nervous system, and other rare and miscellaneous entities. Subarachnoid hemorrhage may result from rupture of an intracranial aneurysm. Other cerebrovascu-

lar accidents including hypertensive hemorrhagic stroke can be lethal. These entities are responsible for most cases of brain death that lead to organ donation. Brain injury after trauma, either vehicular or related to firearms, is also common.

Pathophysiology

Cardiovascular Instability. During the events that lead to brain death, there is usually progressive intracranial hypertension. Important pathophysiologic responses are evident before the actual occurrence of brain death, including the development of marked systemic hypertension associated with vastly increased sympathetic activity and the massive release of catecholamines. Arrhythmia may become manifest at any time during the process of tentorial herniation. Bradyarrhythmia may be associated with the systemic hypertensive response to intracranial hypertension (Cushing reflex), but ventricular and supraventricular tachyarrhythmia may also be seen in the presence of high levels of catecholamines.

Once herniation is complete and brain death has occurred, a high proportion of donors manifest a hypotensive response related to the loss of sympathetic tone and the failure to maintain circulating catecholamine levels. It has been reported that 62% of brain-dead patients sustain cardiac arrest within 24 hours and 87% by 72 hours in the absence of specific donor maintenance measures.²⁶ Even with aggressive donor support, about 10% of donors manifest cardiopulmonary arrest during the interval between the determination of brain death and the procurement of organs.²⁷

Central Hormonal Failure. As the brain and brainstem cease to function, failure of the central hormonal axis occurs. Pituitary hormones cease to be produced, and diabetes insipidus ensues. Without antidiuretic hormone, urinary output may increase to astonishing rates, sometimes well in excess of 1 L/h. The urine becomes extremely dilute, resulting in increasing serum osmolality and hypernatremia. The resultant hypovolemia may contribute to cardiovascular collapse if untreated.

The influence of other aspects of central hormonal function is less well understood. There is experimental evidence of reduced circulating levels of triiodothyronine, cortisol, and insulin after brain death in pigs and baboons.^{28,29} These factors may contribute to the hemodynamic instability, cardiovascular collapse, and hyperglycemia so often seen in association with brain death and have led some to advocate using combinations of these compounds before organ procurement. Confirmatory studies in humans have not shown these hormonal systems to play major roles in the pathophysiology of the hypotensive state following brain death, although use of these agents is still common in clinical practice.

Request for Permission from Next of Kin. All states and the federal government have passed legislation requiring that relatives of deceased patients be asked whether they are willing to permit organ or tissue donation. Unfortunately, the contribution of such laws to an increase in the actual supply of donor organs is less than clear. What is far more important than required request is the careful training, uniform deployment, and empathetic demeanor of the individuals who actually approach the family. In many hospitals, trained donor coordinators are on call to discuss the option of organ donation with bereaved families. Such people may come from a variety of fields, including medicine, nursing, social work, or pastoral care. Refusal of consent by the family is one of the biggest stumbling blocks to increasing the supply of organs actually donated. It has also been suggested that the discussion of possible organ donation should occur at a time subsequent to and separate from informing the family of the patient's death.

The use of the term *brain death* may be confusing to laypeople and professionals alike; it implies that brain death

TABLE 34.1**CLASSIFICATION HIERARCHY FOR PERMISSION FOR ORGAN DONATION FROM NEXT OF KIN**

1. Spouse
2. Adult son or daughter
3. Either parent
4. Adult brother or sister
5. Guardian
6. Any other person authorized to dispose of the body

is different from other kinds of death. Obviously, the distinction is intended to differentiate this modality of dying from cardiac death but not to indicate that the person is any less dead. Phrases such as “keeping the organs alive so they can be transplanted” are as misleading and confusing as they are incorrect.

According to the Uniform Anatomical Gift Act, a signed and witnessed organ donor card is a legally binding indication of the decedent's wishes, but throughout North America and most European countries, the family's consent is routinely obtained before organ procurement. Although it is desirable that the entire family be in agreement about donating, the legal next of kin is required to agree to the donation and grant signed permission (Table 34.1).

Donor Maintenance

Tissue Perfusion. Most donors are maintained with a minimum of fluids to prevent increased cerebral edema, and, therefore, one of the first priorities in donor maintenance should be the prompt restoration of intravascular volume. Depending on the duration of the donor's underlying illness, this process may require from 3 to 10 L of volume resuscitation. In general, the dosage of pressor agents required to support blood pressure can be progressively decreased as the central venous pressure is raised to 10 to 12 cm H₂O. Crystalloid may be used, and lactated Ringer solution is often given because its slightly lower sodium concentration counteracts the concentrating effects of diabetes insipidus. If the latter condition has resulted in severe hypernatremia, the addition of free water may be necessary. Colloid and blood should be used to restore and maintain osmotic pressure and normovolemia. The hematocrit should be kept around 35 volume percent to replace traumatic losses and to maintain oxygen-carrying capacity. Enough volume should be administered to achieve a urine output of at least 100 mL/h and a systolic arterial pressure of 90 to 120 mm Hg. Higher levels of arterial blood pressure are usually unnecessary because the loss of sympathetic tone accompanying brain death facilitates tissue perfusion at lower pressure.

If diabetes insipidus is severe, exogenous vasopressin must be given. Available in a variety of forms, desmopressin acetate, a synthetic analog of 8-arginine vasopressin, appears to have the least splanchnic vasoconstrictive effect compared with its antidiuretic action. This agent can be given by a variety of routes, including intranasally, subcutaneously, or intravenously. The usual dosage is 20 µg intranasally or 2 to 4 µg intravenously or subcutaneously.

Oxygenation and Ventilation. Arterial blood gases should be checked regularly and appropriate adjustments of the ventilator made to optimize gas exchange and acid-base balance. Oxygen supply should be adequate to maintain an arterial oxygen saturation of greater than 95% and mixed venous oxygen saturation above 70%. Low levels of positive end-expiratory pressure may facilitate achieving a balanced oxygen supply and demand.

Inotropic Support. Most donors are hypovolemic at the time of brain death and are receiving inotropic support in lieu of volume to support their blood pressure. Dopamine hydrochloride is the most commonly used agent. The need for dosages above 10 µg/kg/min usually indicates persistent hypovolemia, and the restoration of normovolemia is almost always accompanied by a reduction in dopamine requirements. High doses of dopamine maintained for long periods before organ procurement may be associated with increased rates of acute tubular necrosis and hepatic allograft failure. Cardiac procurement is often abandoned if high doses of inotropic support are required despite adequate volume status.

Other inotropic agents, such as isoproterenol, epinephrine, norepinephrine, and phenylephrine, are occasionally used, but the use of these agents should be discouraged because of their peripheral vasoconstrictive effects. Dobutamine is sometimes used in conjunction with low doses of dopamine.

Prevention of Hypothermia. Thermoregulatory homeostatic mechanisms are destroyed with the occurrence of brain death, and the development of severe hypothermia may lead to ventricular arrhythmia and cardiac arrest. Warming blankets should be used above and below the donor to keep body temperature above 35°C, and exposure for the purposes of examination or intervention should be kept to a minimum. If maintenance of normal body temperature is problematic, intravenous fluids may be prewarmed before administration, and a heated humidifier circuit can be added to the ventilator.

Multiple Organ Procurement

The Organ Procurement and Transplantation Network and the Coordination of Surgical Teams. When brain death has been declared, the person has been identified as a suitable organ donor, and permission has been given by the next of kin, the logistics of organ procurement must be arranged. Since passage of the National Organ Transplantation Act, a national Organ Procurement and Transplantation Network (OPTN) has been organized. The federal contract for this important function is held by the United Network for Organ Sharing (UNOS). The OPTN is responsible for the fair and equitable distribution of deceased donor organs throughout the United States. The 50 states and U.S. territories and possessions are divided into 11 regions (Fig. 34.4). Within each region, federally certified local organ procurement organizations (OPOs) are responsible for maintaining the list of potential recipients for their catchment area. All transplant candidates within the United States are entered into a computer system, and an allocation system is used to determine the appropriate potential recipient for a given donor organ. In general, offers are made first to candidates listed with transplant centers in the local OPO service area, then to suitable candidates in the region, and finally to any candidate in the nation. In each case, priority is ordered by the existing allocation system designed for that organ.³⁰ An important exception to these general rules relates to renal transplant recipients who share six antigens with the donor. These kidneys are automatically shared nationwide even if suitable local recipients are available.

Recipients of the various organs may reside in geographically distant locations. Because the recipient transplant teams must be given considerable detailed information about the donor to decide whether to use a particular organ for a particular recipient, a finite period of time is required to assemble the necessary donor retrieval teams. A national computerized system (DonorNet) provides all relevant medical information simultaneously to multiple prospective accepting programs. The coordinating OPO contacts accepting teams, facilitates logistical arrangements and communications for travel to the donor hospital, and makes arrangements for the

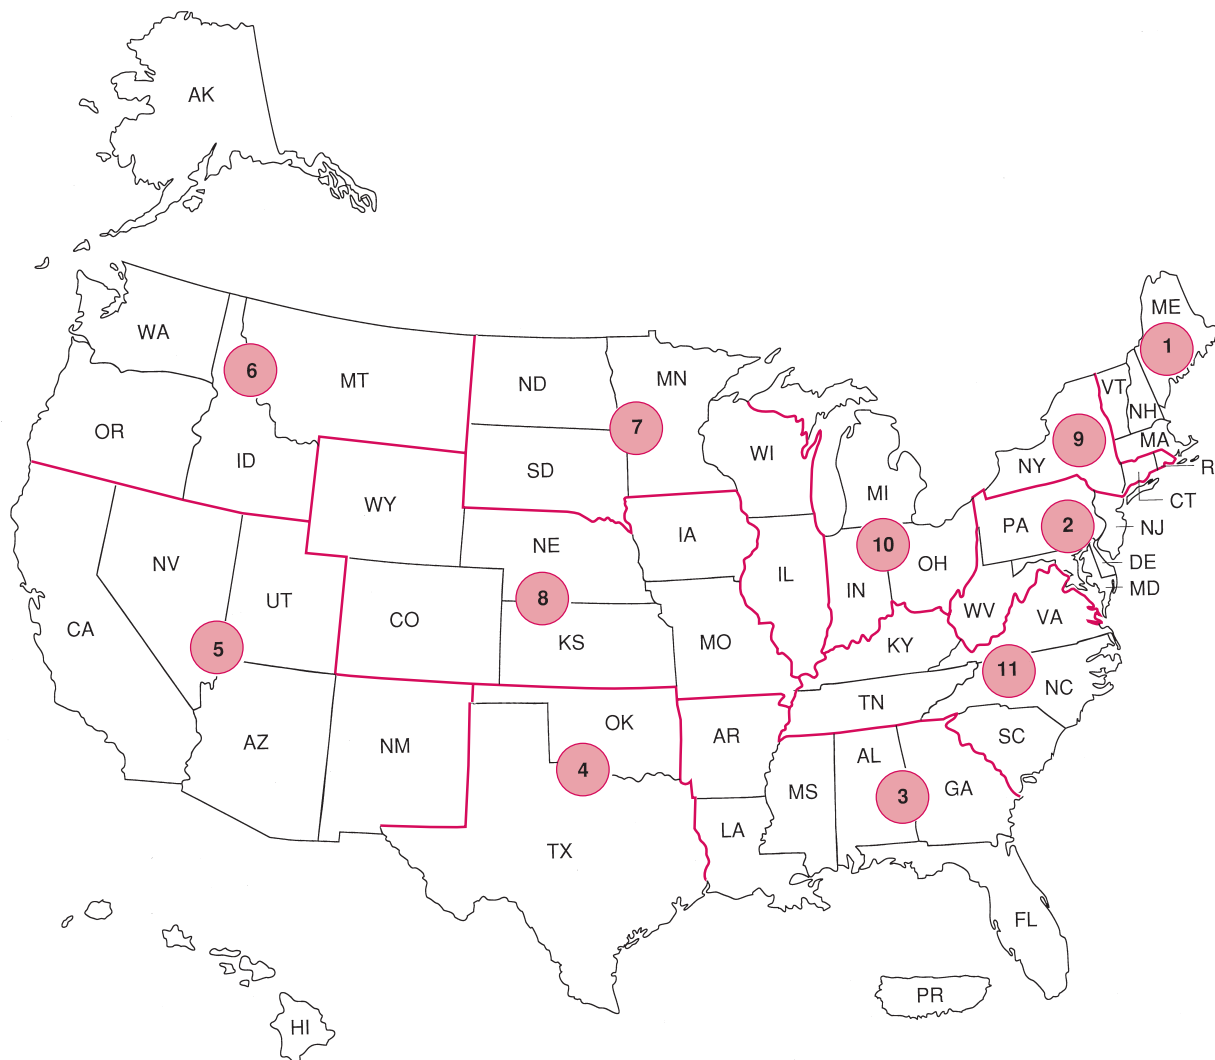

FIGURE 34.4. The 50 United States are divided into 11 regions of approximately equal populations for purposes of administration of organ procurement, distribution, and educational objectives.

donor operating room to be available at an appropriate time. When all teams are on site at the donor hospital, the donor is transferred to the operating room for the actual procurement procedure.

Surgical Technique for Multiple Organ Procurement.

Techniques of multiple organ procurement allow for the removal of the heart, lungs, kidneys, liver, intestine, and pancreas from a single donor for transplantation into multiple recipients. The following discussion details the methods used to remove all these organs from a donor.

The heart-beating donor is brought to the operating room from the ICU or emergency department with appropriate hemodynamic and electrocardiographic monitoring. Oxygen is delivered by hand bagging at 100% inspired concentration. Inotropic drug infusions are continued during transport and procurement. The anesthesiologist should maintain close communication with the procurement teams to avoid the development of cardiac arrhythmia, hypotension, and hypoxemia. The procuring surgical teams should each confirm documentation of the declaration of death, valid consent for organ donation, and ABO blood typing.

The steps in the procedure can be categorized as follows: (a) incision, (b) exploration and inspection, (c) individual

organ mobilization, (d) in situ perfusion, (e) removal of organs, and (f) closure of the incision. Postprocurement processing, packaging, and transport to the recipient centers are the final steps.

The entire torso is prepared with an iodine-containing solution, and a field is draped from the neck to the pubis. A long, midline incision is made from the suprasternal notch to the pubis. The sternum is split with an electrical or air-powered saw if available, although manual methods using a Lebsche knife or Gigli saw work perfectly well. Exposure of the abdominal organs may be facilitated by the addition of cruciate incisions (Fig. 34.5). A general exploration is carried out to ascertain that no unexpected conditions are present that would preclude donation, such as tumor, infection, or specific organ damage. In general, a “no-touch” technique is used to minimize trauma to the organs during the procurement procedure.

For the so-called rapid technique of organ procurement, relatively little in the way of mobilization of individual organs is necessary. Preparation for in situ perfusion consists of a complete Kocher maneuver, with mobilization of the right colon, duodenum, and small bowel in a cephalad direction to the patient’s left (Fig. 34.6). The aorta is exposed from the bifurcation distally to the level of the left renal vein

FIGURE 34.5. A complete midline incision from suprasternal notch to pubis is made for multiple organ procurement. The sternum is split. If necessary, cruciate abdominal incisions are added to facilitate exposure of the intra-abdominal organs.

FIGURE 34.6. The Kocher maneuver is used to mobilize completely the right colon and duodenum, exposing the retroperitoneum, including the aorta, from the level of the superior mesenteric artery to the bifurcation and the inferior vena cava from the iliac veins to the edge of the liver.

FIGURE 34.7. A: The left triangular ligament is divided and the left lateral segment of the liver is retracted to expose the esophagus and aortic hiatus. B: The pars flaccida of the lesser omentum is widely opened after checking for the presence of a replaced left hepatic artery arising from the left gastric artery. C: After division of the diaphragmatic crura, the supracoeliac aorta is encircled at the level of the diaphragm.

proximally. The inferior mesenteric artery may be divided. Lumbar branches may be ligated and divided at this point. The inferior vena cava is similarly exposed. Next, the left triangular ligament of the liver is taken down, exposing the crural fibers at the aortic hiatus. The aorta is encircled with a tape at the diaphragm (Fig. 34.7A). These maneuvers can be

accomplished in 10 to 15 minutes and allow in situ perfusion through the distal aorta and cross-clamping of the proximal aorta to begin immediately in the event that the donor becomes hemodynamically unstable or sustains cardiac arrest. Warm ischemia is completely prevented by in situ perfusion.

FIGURE 34.8. A: Standard hepatic arterial anatomy, with the artery arising as a single vessel as a branch of the celiac axis. B: Aberrant hepatic arterial anatomy, with a replaced right hepatic artery arising from the superior mesenteric artery and ascending posterior to the common bile duct and anterolateral to the portal vein. C: A replaced left hepatic artery arising from the left gastric artery is usually visible and palpable crossing the pars flaccida of the lesser omentum from the lesser curvature of the stomach. D: A completely replaced common hepatic artery arising from the superior mesenteric artery.

Stable donors afford the luxury of further preparation before in situ flushing. The inferior mesenteric vein is isolated as it enters the retroperitoneum behind the pancreas. This vein provides convenient access for in situ portal flushing by means of a small catheter. If pancreas and/or intestinal procurement is also planned, the portal flush can be done after removal. The pars flaccida of the lesser omentum should be inspected for evidence of a replaced left hepatic artery arising from the left gastric artery, and minimal dissection of the hepatic artery is necessary (Fig. 34.7B). The portal triad should be palpated

carefully for evidence of a replaced right hepatic artery arising from the superior mesenteric artery. This vessel, when present, can be palpated as it courses toward the liver posterior to the common bile duct and along the right side of the portal vein as it emerges from its origin off the superior mesenteric artery posterior to the pancreas (Fig. 34.8).

If the pancreas is to be procured, 250 mL of an iodine-containing solution, followed by instillation of an antifungal agent, is administered via the nasogastric tube into the duodenum. After the gastrocolic omentum is divided, the short

FIGURE 34.9. **A:** Division of the gastrocolic omentum exposes the pancreas. The short gastric vessels are ligated and divided, separating the spleen from the stomach. **B:** After completion of gastric devascularization, the duodenum is stapled just beyond the pylorus and the stomach is retracted superolaterally to facilitate exposure and mobilization of the pancreas.

gastric vessels are carefully divided between ligatures or hemostatic clips. The left and right gastric branches to the stomach are then divided. After the nasogastric tube is withdrawn from the duodenum, a stapling device is applied just beyond the pylorus (Fig. 34.9). The spleen is delivered anteriorly, dividing its attachments to the body wall and diaphragm. Using the spleen as a handle, the retroperitoneal attachments of the pancreas are divided from lateral to medial, until the superior mesenteric vessels are reached (Fig. 34.10). The distal duodenum is divided with a stapler near the Treitz ligament just before or after aortic cross-clamping.

If the intestine is to be procured for an isolated small bowel transplant, the only additional dissection required is to separate the distal ileum near the ileocecal valve from the colon. The small bowel is transected here using a stapling device.³¹

The course of the ureters should be identified. The Gerota fascia is widely incised to allow topical cooling with iced slush solution to supplement the in situ perfusion. Complete mobilization of the kidneys before in situ flushing is unnecessary and risks damage to the renal vessels or inadvertent division of accessory renal arteries.

The heart and lungs can be readied for removal by a team working simultaneously with the abdominal retrieval team. The superior and inferior vena cavae are mobilized, and the aortic arch is dissected sufficiently for the placement of a cross-clamp at the time of infusion of aortic root cardioplegia (Fig. 34.11). Preliminary mobilization of the lungs is usually per-

formed, and access to the pulmonary artery is necessary for pulmonary preservation.

When all teams are ready, a coordinated sequence of events ensures that all organs are simultaneously cooled and protected. The donor is systemically heparinized. At this point, if in situ portal flushing is desired, a catheter is advanced through the inferior mesenteric vein near the pancreas into the portal vein (Fig. 34.12A). A cardioplegia needle is positioned in the aortic arch (Fig. 34.12B). The distal abdominal aorta is cannulated for retrograde in situ perfusion of the kidneys, liver, pancreas, and intestine, and an exsanguination cannula is placed in the distal inferior vena cava (Fig. 34.12C). Alternatively, the inferior vena caval–right atrial junction may be divided in the chest with suction catheters placed in the caval lumen and right thoracic cavity to decompress the venous circulation at the moment of aortic cross-clamping.

The aortic arch and the abdominal aorta at the diaphragm are simultaneously cross-clamped. Cardioplegia solution is infused under pressure into the aortic root, perfusing the coronary arteries and arresting the heart. Ventilation is ceased. Portal and distal aortic perfusion are initiated with ice-cold preservation solution. Topical iced slush is placed in the abdomen and chest to assist the cooling process. The heart and lungs are then removed. The clamp is removed from the distal vena caval cannula for exsanguination and to preclude venous congestion. The liver and pancreas are removed en bloc. The diaphragm surrounding the suprahepatic inferior

FIGURE 34.10. The pancreas is reflected anteriorly and to the right to the level of the superior mesenteric vein near the confluence with the splenic vein. The aortic origins of the celiac axis and superior mesenteric arteries are identified.

vena cava and adjacent to the bare area of the liver is divided. The infrahepatic inferior vena cava is divided just cephalad to the left renal vein. The liver and pancreas unit is now attached only by the distal superior mesenteric vessels coursing to the small bowel and by the aortic origins of the superior mesenteric artery and celiac axis. The superior mesenteric artery

and vein emerging from the uncinate process are ligated and divided, and a cylinder of aorta is removed encompassing the superior mesenteric artery and celiac axis. The distal superior mesenteric artery and vein provide blood supply to the small intestinal graft, which is removed next. The liver and pancreas are separated as a bench procedure, retaining the celiac

FIGURE 34.11. Preparation of the heart for cardioplegia. Minimal dissection is necessary. The venae cavae are encircled, and the aorta is separated from the pulmonary artery.

FIGURE 34.12. In situ perfusion set-up. **A:** A cannula is placed into the portal vein through the inferior mesenteric vein for portal venous perfusion. **B:** A needle is placed in the aortic root for perfusion of the coronary arteries with cardioplegia solution. **C:** A cannula is placed in the distal aorta for retrograde perfusion with cold preservation solution. Another cannula is placed in the distal vena cava for venous decompression and exsanguination.

axis with the liver (Fig. 34.13). The splenic artery is divided at its origin. This vessel and the superior mesenteric artery are reconstructed with a bifurcated donor iliac artery graft. The portal vein is divided about 1 cm from the pancreas. The common bile duct is divided at the superior edge of the pancreas.

The kidneys are also removed en bloc. The ureters are given wide berth to avoid devascularization and are divided near their entrance into the bladder. Dissection is carried out posterior to the aorta and vena cava in the plane of the prevertebral fascia. Once removed, the left renal vein is divided flush with the vena cava (Fig. 34.14). The aorta is opened in the midline to identify the orifices of the renal arteries from within the lumen. In this way, multiple renal arteries can be readily identified and kept on a single aortic Carrel patch. Once the abdominal and thoracic organs have been removed, a sampling of lymph nodes and spleen is taken for tissue typing and cross match testing. The chest and abdomen are closed, and standard postmortem care is given.

Donation after Cardiac Death

The profound shortage of organs has led to efforts aimed at utilizing organs from patients who die as a result of cardiac standstill rather than brain death. This process is referred to as

donation after cardiac death (DCD). Individuals who are declared dead in the emergency department without cardiac function are not generally used as donors because the hemodynamic situation is uncontrolled. In contrast, patients who have severe brain injury but who do not meet brain death criteria can be considered as controlled DCD donors. In this setting, a decision to withdraw further life support measures has already been made by the family and the treating team of physicians. DCD, especially of kidneys and increasingly of livers, has become one of the fastest-growing sources of donor organs.³² Once the decision to withdraw support has been made, organ donation can be considered. The Institute of Medicine has studied the issues surrounding the utilization of DCD donors and recommends that “the recovery of organs from non-heartbeating donors is an important medically effective and ethically acceptable approach to reducing the gap that exists now and will continue to exist in the future between the demand for and available supply for transplantation.”³³

Following informed consent, perfusion and exsanguination cannulae are placed in the femoral artery and vein, respectively. The patient is then extubated and must expire, usually within 60 minutes, in order for the donation to proceed. This agonal period may be accompanied by marked hypotension and desaturation, and typically results in some degree of warm ischemic injury. The Institute of Medicine recommends

FIGURE 34.13. The liver and pancreas are removed en bloc. Separation of the two organs is accomplished as a bench procedure. The celiac axis is retained with the liver, dividing the splenic artery just beyond its origin. The gastroduodenal artery is ligated and divided. The portal vein is divided approximately 1 cm from the superior edge of the pancreas, and the common bile duct is divided just superior to its entrance into the pancreas.

waiting an additional 5 minutes after cessation of effective cardiac function and pronouncement of death before proceeding with organ procurement.

At this point, the organs are rapidly cooled by infusing cold preservation fluid via the previously placed cannula. Simultaneously, the abdomen and chest are opened and a standard organ procurement procedure is carried out. Growing experience demonstrates that outcomes of kidneys transplanted from DCD donors are comparable with those from brain-dead donors, with the exception of a higher incidence of delayed graft function.³⁴ However, DCD livers have been noted to develop ischemic-type biliary strictures, and significantly worse outcomes from livers from DCD versus brain-dead donors have been reported.³⁵

Current Preservation Techniques and Results

Kidneys, Liver, and Pancreas. For many years, the primary solution used for cold storage preservation of the kidneys was Euro-Collins solution (Table 34.2). This formulation provides a hyperosmolar environment with intracellular electrolyte composition that is intended to reduce cellular swelling. In combination with hypothermia, kidneys can be safely stored in this solution for 36 to 48 hours before transplantation.

In the 1980s, the advent of new immunosuppressive agents, such as cyclosporine, meant that for the first time extrarenal organs could be transplanted with good success rates, and the

FIGURE 34.14. The kidneys are removed en bloc and separated on the back bench. Safe division is ensured by viewing the kidneys posteriorly. The aorta is divided between the paired lumbar arteries, and renal arterial orifices can be viewed directly from within the aortic lumen. This avoids any hilar dissection with the accompanying risk of injury to renal arteries. The left renal vein is divided at its entrance to the inferior vena cava, leaving the entire vena cava with the shorter right renal vein.

TABLE 34.2**COMPOSITION OF HYPOTHERMIC ORGAN PRESERVATION SOLUTIONS**

■ COMPONENT	■ AMOUNT PER LITER
Euro-Collins Solution	
KH ₂ PO ₄	2.05 g
K ₂ HPO ₄	7.4 g
KCl	1.12 g
NaHCO ₃	0.84 g
Glucose	35 g
University of Wisconsin Solution	
K ⁺ -lactobionate	100 mmol
KH ₂ PO ₄	25 mmol
MgSO ₄	5 mmol
Raffinose	30 mmol
Adenosine	5 mmol
Glutathione	3 mmol
Insulin	100 IU
Penicillin	40 IU
Dexamethasone	8 mg
Allopurinol	1 mmol
HTK Solution	
NaCl	15 mmol
KCl	9 mmol
KH-2-ketoglutarate	1 mmol
MgCl ₂	4 mmol
Histidine hydrochloride	18 mmol
Histidine	180 mmol
Tryptophan	2 mmol
Mannitol	30 mmol
CaCl ₂	0.015 mmol

need for more effective preservation became apparent. Cold ischemia limitations of about 8 hours for the liver and pancreas meant that donor and recipient teams had to be exquisitely coordinated; complex recipient operations requiring a multitude of ancillary support services had to be organized in the middle of the night; and all personnel involved in the procedure, including the surgeons, were starting the operation in a fatigued condition.

A solution was developed that transformed the practice of hepatic and pancreatic transplantation. This solution includes lactobionate, raffinose, hydroxyethyl starch, and a host of other ingredients designed to provide high-energy phosphate precursors, hydrogen ion buffering capacity, and antioxidant properties. It is unclear how many of these components are truly necessary. Lactobionate, an impermeant anion to prevent cellular swelling, is used in place of the glucose that is contained in Euro-Collins solution; raffinose, a naturally occurring trisaccharide of fructose, glucose, and galactose, which is found in abundance in sugar beets, provides additional osmotic activity; and hydroxyethyl starch is a colloid intended to prevent an increase in the extracellular space. The University of Wisconsin (UW) solution is used to preserve most organs in the United States. Livers and pancreata can be stored for up to 24 hours, and isolated clinical cases with total cold ischemia times in excess of 30 hours have been reported.^{36,37} However, although livers will function in terms of hepatocellular metabolism, evidence is accumulating that cold ischemia times of greater than 12 hours may be associated with a higher incidence of biliary strictures. The propor-

tion of liver transplants with cold ischemia time above 10 hours has decreased steadily over the period from 1997 to 2006 from 23% to 11%.¹³

It is not clear whether UW cold storage solution has any significant advantages over Euro-Collins solution for the preservation of kidneys. In a large, randomized, multicenter European trial, patient and graft survival rates were similar among recipients of the two solutions, but the incidence of delayed graft function requiring dialysis was reduced by about one third in the UW group. The results of other ongoing trials are needed before a definitive statement can be made about the relative merits of the two solutions in renal preservation. This point may be moot, however, because the majority of deceased donors are used for the procurement of extrarenal organs as well as kidneys, so UW solution is generally used for all of the abdominal organs.

A newer preservative solution, histidine-tryptophan-ketoglutarate (HTK) solution, has been reported to have advantages over UW solution in terms of reduced viscosity.³⁸ However, recent analyses of outcomes after deceased donor kidney and liver transplants have suggested inferior results using this preservation solution.^{39,40}

There has been a resurgence of interest in pulsatile machine preservation for donor kidneys. Many studies have attempted to discern whether this technique results in superior preservation characteristics. However, there is a large practice pattern effect, and treatment indication bias has confounded most studies to date. Recently, however, a European prospective randomized trial has shown significantly better results using machine preservation.⁴¹ However, because of the added expense and logistical requirements for machine preservation, further studies are needed to identify which donor kidneys are best suited to this technique.

Heart and Lungs. Cardiac preservation has changed relatively little in recent years. Crystalloid cardioplegia solution is used at 4°C, and 4 hours is the generally accepted limit of cold ischemia. For this reason, donor and recipient operations must be finely coordinated. Recently, machine perfusion preservation has been explored as an alternative to simple cold storage, but this modality is still considered experimental.

A comprehensive review of pulmonary preservation has recently been published.⁴² Hypothermia is used along with intracellular-type solutions such as Euro-Collins or UW solution. Pulmonary inflation is also important. The optimal vascular perfusate for the lungs remains unknown, however, and results with pulmonary transplantation are still limited by deficiencies in the quality and duration of preservation.

Small Bowel. Transplantation of small bowel segments with or without concomitant liver transplant is being performed more commonly as a definitive treatment for short-gut syndrome. Preservation of the bowel is generally performed with UW solution or HTK solution.⁴³ Since most small bowel procurements are from donors that have multiple transplantable organs, standard in situ intra-aortic preservation techniques are used. The current limit of cold ischemia time for small bowel is approximately 12 hours.⁴⁴

CHAPTER 35 ■ RENAL TRANSPLANTATION

CHRIS FREISE AND PETER STOCK

KEY POINTS

- 1 The major barriers to successful renal transplantation include ABO compatibility and the HLA system.
- 2 Before a renal transplant is undertaken, histocompatibility of the donor and recipient are determined.
- 3 Methods to expand the donor pool of kidneys include the use of donation after cardiac death and expanded criteria donors.
- 4 The etiology of kidney disease resulting in end-stage failure, and the necessity for transplantation is led by glomerulonephritis, diabetes, and hypertension.
- 5 Surgical complications of kidney transplantation include vascular, urologic, lymphocele, and wound problems.
- 6 The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa.
- 7 Hyperacute rejection is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney.
- 8 Acute cell-mediated rejection most typically occurs between 1 week and 3 months following transplantation.
- 9 Chronic rejection leads to loss of graft function over the course of months to several years.

Renal transplantation has evolved to become the preferred therapeutic modality for patients with end-stage renal failure. Improved patient survival and quality of life as compared with dialysis has been established, with cost effectiveness achieved after a minimum of 18 months of allograft function. The importance of minimizing time on dialysis, compounded by the exponential growth of patients on the wait list, has led to several strategies to increase the number of deceased and living donor organs in an effort to decrease waiting time and mortality on the wait list. These new strategies have been the focus of clinical research in kidney transplantation and will be discussed in this chapter. Other important topics that will be reviewed include immunologic considerations specific to kidney transplantation; preoperative assessment of kidney allograft recipients; the standard surgical approach in kidney transplantation and advances in laparoscopic technology for the donor; current strategies in immunosuppression; management of the technical and immunosuppressive complications; and future trends.

IMMUNOLOGY OF RENAL TRANSPLANTATION

The immunologic response to allografted tissue is well defined and under the influence of both T-cell- and B-cell-derived reactions. The cells and cytokines responsible for rejection vary with time posttransplant (hyperacute, acute, and chronic rejection) and have a differential response to currently available immunosuppressive agents.

1 The major barriers to successful renal transplantation include ABO compatibility and the human leukocyte antigen (HLA) system. In general, renal transplantation is done between ABO-compatible donor and recipients using the same guidelines as for blood transfusion. However, because of the shortage of donors, cadaver kidneys are nearly always used in recipients of identical blood type. Recently, ABO-incompatible living-donor transplants have been performed on an experimental basis secondary to excessive wait times for ABO-compatible deceased-donor transplants.^{1,2}

The HLA system is made up of well-defined antigens present on most cell types that are genetically determined for each patient and are termed the *major histocompatibility complex*. These genes reside on chromosome 6 and are distributed in a Mendelian fashion to offspring. The HLA system includes several loci, but the most commonly characterized are the HLA-A, HLA-B, and HLA-D regions. Given that each human has two alleles for each locus, there are six potential HLA antigens of clinical significance. These are characterized using tissue typing techniques and can be used to determine the degree of matching between a donor and potential recipient, i.e., one-antigen match to six-antigen match. Improved results of graft survival are seen when the degree of matching reaches the six-antigen level, and long-term results may be better with matching to a lesser degree.

Class I antigens include the HLA antigens A, B, and C, whereas class II antigens include the D and DR loci. Class I antigens act as targets for cytotoxic T lymphocytes, and class II antigens are important for antigen presentation. Class II antigens are also responsible for triggering lymphocyte proliferation in the mixed lymphocyte culture system.

2 Before a renal transplant is undertaken, histocompatibility of the donor and recipient are determined. Standard testing consists of two procedures. Donors and recipients first undergo tissue typing, which involves characterization of their respective HLA type. Recipient serum is tested against a panel of antigens that contain the known HLA types, to identify anti-HLA antibodies. The sensitivity for detecting anti-HLA antibodies continues to improve, and newer technology uses single antigen beads to detect antibodies against a specific HLA antigen. The amount of reactivity that a potential recipient has against a

panel of HLA antigens is indicative of the degree of sensitization. Based on the number of anti-HLA antibodies detected, a calculated percent reactive antibodies (cPRA) can be estimated. A cPRA of 70% would suggest that the potential recipient would have anti-HLA antibodies against 70% of the potential donor pool. Sensitization to HLA antigens occurs as a result of previous exposure to foreign HLA antigen either from pregnancy, previous blood transfusion, or a previous organ transplant. A patient who is highly sensitized is more difficult to transplant because of the greater likelihood of having antibodies to a potential donor.

The second test performed prior to transplantation is commonly known as the *final cross-match*. Several recipient serum samples collected at different times are mixed with donor lymphocytes in a culture system. This assay will detect preformed cytotoxic antibodies that would result in a hyperacute rejection if the transplantation were performed (see Rejection, later). A more sensitive method of detecting these antibodies uses a fluorescent activated cell scanner and is commonly used when evaluating potential recipients who are highly sensitized or receiving second transplants. In the near future, many transplant centers will be adopting a “virtual cross-match” based on the detection of anti-HLA antibodies present in a given recipient. The most sensitive technology will be used to detect the presence of anti-HLA antibodies in a given recipient. Based on these antibodies, each recipient will have a list of unacceptable donor antigens. Compatibility with each donor will be determined in the absence of the final cross-match by eliminating a potential donor based on the presence of unacceptable antigens. This strategy facilitates an expedited transplant and minimization of cold ischemia times, as it avoids the additional time and expense associated with the final cross-match. Widespread acceptance of the virtual cross-match will require further confirmation that all donor antigens are sufficiently identified using the single antigen bead technology.

THE DONOR POOL: LIVING DONORS, DECEASED DONORS, DONATION AFTER CARDIAC DEATH

There is marked improvement in graft survival for both living and deceased donors when a transplant can be completed before the initiation of dialysis.³ The significantly better outcomes achieved with preemptive transplantation and minimization of dialysis times have given rise to several strategies to increase the number of available kidneys.

Living Donors

The first long-term success in renal transplantation over 50 years ago involved a live donor transplant between twin brothers. The number of living donors has increased significantly in the last few years, in part as a result of the increased use of the laparoscopic technique for donor nephrectomies. For the first time, in 2001 the number of living donors exceeded the number of deceased donors, although deceased donor transplants still represent the majority of kidney transplants done today.⁴ This trend toward increased live donation may also be the result of the excessive waiting times for deceased donor transplants, now more than 7 years for blood type O and B recipients in many parts of the United States. Despite initial concerns about the safety and efficacy of the laparoscopic technique for the donor procedure, morbidity and mortality rates (0.03%) remain low and comparable with those of the open technique.^{5,6}

The evaluation of a potential living kidney donor begins with a brief overall assessment of physical condition because

potential donors must be in good health with normal kidney function. Diabetes, hypertension, and cardiovascular disease generally rule out a potential donor. ABO is also determined before further workup, because ABO incompatibility has been a relative contraindication to donation. A cross-match test is usually performed at this time to ensure donor and recipient immunologic compatibility. After this initial screen, a careful medical and psychosocial screen takes place to confirm donor suitability. Following a normal physical examination, further studies should include chest radiography, electrocardiogram, urinalysis, and blood work. During this phase, any conditions that could predispose to later renal insufficiency need to be ruled out. For example, donors from families with a history of type II diabetes are at a significant risk for the development of diabetes, and glucose tolerance testing is justified as part of the screening process. A history of renal stones warrants stone analysis to assess likelihood for recurrent stones. Any inherited disorders of kidney disease must also be ruled out, particularly in potential living-related donors when the recipient has polycystic kidney disease.

The psychosocial history is directed at assessing the motivation of the donor, and to ensure that there are adequate resources for the donor to proceed with the surgery and recovery. Many centers require a relationship between the donor and intended recipient, although it is becoming increasingly common to have general members of the public show interest in being evaluated as a donor, with no particular recipient identified. These nondirected donors require the same careful scrutiny as any living donor, and the psychosocial evaluation is especially important. The motivation for donation should be clear and not be connected in any way to financial gain. It is also the duty of the physician evaluating the potential donor to review the current statistics on morbidity and mortality, and the potential donor should be provided with the opportunity to speak to the transplantation team privately to address issues of reluctance or coercion. To allow for an unbiased assessment of the donor, it is now required that an independent donor advocate be part of the evaluation team, and by definition this person should have no role in the care of an intended recipient.

The final testing of a potential donor involves anatomic definition of the two kidneys and is typically done with either a computed tomography angiogram or MR angiogram, both of which avoid the needle stick and catheters associated with a conventional angiogram. The results of these studies are used to detect any anatomic abnormalities that would exclude a donor and to decide which kidney will be removed. In general, the left kidney is favored for transplant because it has a longer renal vein.

Several strategies are currently being considered to increase the frequency of living donation. Potential donors with well-controlled hypertension on a single antihypertensive agent are being considered, although this remains controversial. Controversy also exists regarding the potential reimbursement for living donors, specifically providing financial compensation regarding lost wages during the donation. Consideration is also being given to providing health insurance to living donors for complications related to the donor procedure. The extent of the reimbursement provided to living donors continues to be debated by medical ethicists and transplant professionals. Finally, a national exchange system is currently being designed that matches living donors who were incompatible with their intended recipient with other recipients with incompatible living donors. Such exchange systems have already been successful on a regional level, and extending this to a national system will permit many more successful exchanges and further expand the living donor pool.

Deceased Donors

Procurement of kidneys from brain-dead deceased donors has not increased at the same pace as the rapid growth of the national wait list (Fig. 35.1). Although most deceased donors are brain dead, there has been an increased use of kidneys from donors who do not meet the strict definitions of brain death but have cardiopulmonary support withdrawn because of a severe brain injury or high spinal cord injury, with little hope of living without the use of ongoing mechanical ventilation and/or the possibility of existing in a persistent vegetative state. Organs are recovered after withdrawal of support, once the heart stops beating, hence the terminology of *donors by cardiac death* or *DCD donors*. Usually support is withdrawn in a controlled setting so that the time of warm ischemia and poor organ perfusion can be minimized. Minimizing the time from cessation of the heart to perfusion of organs with preservation fluid requires an experienced procurement team, and the successful use of these organs is dependent on rapid procurement. Although the use of livers from DCD donors appears to be associated with a higher incidence of biliary tract complications following transplantation, kidneys procured from DCD donors are proving to be an important source of donor kidneys.⁷ Several studies from the United States and Japan have demonstrated comparable graft success between kidneys procured from DCD donors and brain-dead donors. The percentage of DCD donors in the United States has progressively increased over the last decade and presently represents about 10% of deceased donors.

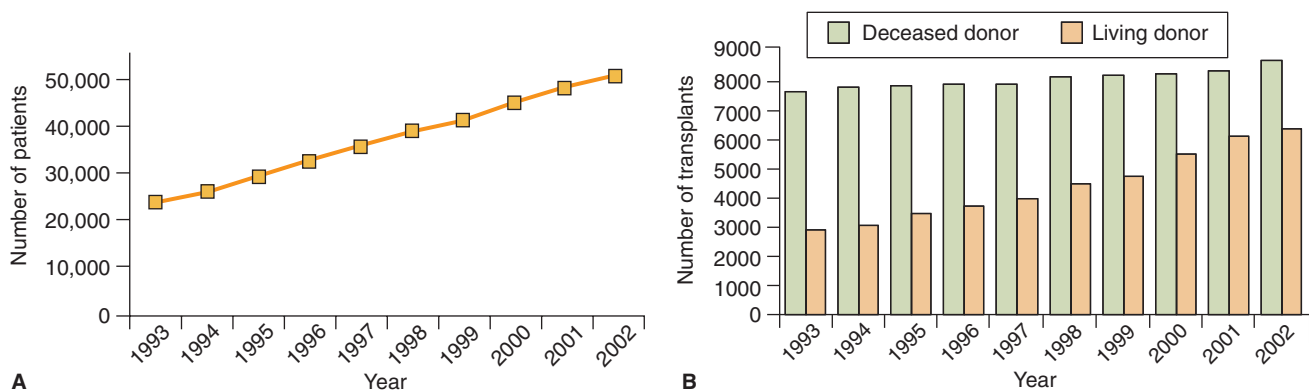

FIGURE 35.1. The growth in the number of patients awaiting transplant (A) has exceeded the relatively stagnant rate of deceased donor kidney transplants leading to progressively increasing waiting times over the last decade. Living donors have had a slight increase, which may be in part due to the introduction of the laparoscopic donation procedure. There has been an increase in the proportion of recipients aged 50 years and older on both the wait list and receiving transplants (B). (Adapted from Wolfe RA, Merion RM, Roys EC, et al. Trends in organ donation and transplantation in the United States, 1998–2007. *Am J Transplant* 2009;9:869–878, with permission.)

Placement of deceased donor kidneys is guided by a series of complex allocation rules established by the United Network for Organ Sharing (UNOS). Unfortunately, the number of people being added to waiting lists continues to be significantly greater than the number of people being removed following transplantation. As a result, waiting times in many parts of the country for blood type O kidneys are exceeding 7 years, and are getting longer each year. To accommodate the increasing size of the waiting lists, the UNOS kidney committee is in the process of establishing a new algorithm for the allocation of deceased donor kidneys. The current system is driven principally by waiting time, with a much smaller component driven by HLA-DR matching. A newer system is being developed that will address the changing demographics of both the patients on the waiting lists and deceased donors, most notably the increasing age of both donors and recipients. At the same time, a new allocation system must balance the conflicting goals of all the stakeholders involved in transplant process, while striking the best balance between justice and utility. As a result of the conflicting goals of all the stakeholders involved in kidney transplantation, the development of a new allocation system continues to be a hot topic of debate within UNOS and the transplant community.⁸

Further Strategies for Increasing the Number of Donor Kidneys

Many of the unique approaches for increasing the number of potential donors have come from Japan, where cultural beliefs have limited the number of available deceased donor transplants. Several groups have reported successful kidney transplantation across ABO blood group barriers, using aggressive pretransplant immunosuppression, plasmapheresis to decrease anti-ABO titers, and in some cases splenectomy.^{1,2} This strategy has been implemented with increasing frequency in the United States as a result of the marked increases in the waiting times for blood group O and B recipients.⁹

An important strategy currently being implemented in the United States as well as internationally involves the use of intravenous gammaglobulin to facilitate transplantation across a known positive anti-HLA cross-match. This protocol could potentially impact the increasing number of sensitized patients on waiting lists with little hope of finding a compatible donor.¹⁰

Further strategies have recently been implemented to expand the availability of kidneys procured from deceased donors. In addition to the use of kidneys from DCD donors described earlier, another strategy recently implemented by UNOS involves expedited placement of kidneys from donors that are less than optimal. These kidneys are designated as *expanded criteria donors* (ECD) and are expected to have decreased graft survival compared with kidneys procured from the standard pool of deceased donor kidneys, designated as *standard criteria donors*. The classification of an expanded criteria donor kidney is based on the presence of older donor age, higher donor creatinine at the time of organ procurement, cerebrovascular accident as the cause of brain death, and a history of hypertension in the donor. The kidneys that fall into the category of expanded criteria donor kidneys are generally allocated to older recipients to decrease their time on the wait list and to improve their overall chance of survival. Expedited placement of these kidneys and rapid transplantation to decrease cold-ischemia time minimizes the potential for delayed graft function and increases the use of organs that otherwise would be discarded.^{11,12}

THE TRANSPLANT PROCEDURE

Recipient Preoperative Assessment

- 4 The etiologies of kidney disease resulting in end-stage failure and the necessity for transplantation are led by glomerulonephritis,

diabetes, and hypertension (Table 35.1).¹³ Because of the high incidence of cardiovascular disease associated with many of these conditions, most notably diabetes, a careful assessment of the cardiovascular status of the potential recipient is critical. For patients at risk, this assessment should include at a minimum an echocardiogram and an exercise or pharmacologic stress test as a screen for reversible ischemia requiring cardiac catheterization. Controversy remains with regard to the accuracy of noninvasive studies in terms of identifying significant disease of the coronary arteries, particularly in diabetic patients. Nonetheless, for most centers this remains the standard screening strategy, and updated studies should be obtained within 1 year of the transplant procedure. If either coronary artery bypass or stenting has taken place in preparation for renal transplantation, follow-up angiograms and/or stress tests should be repeated within 1 year of the actual transplant.

Although the evaluation of potential recipients is focused on the assessment of cardiovascular status, further studies must exclude malignancies and infections that would contraindicate transplantation and immunosuppression. Potential kidney recipients who are infected with hepatitis C should be

evaluated by a hepatologist to determine the risks of immunosuppression causing progression to end-stage liver disease. Potential kidney recipients with evidence of advanced liver disease should be evaluated for a combined liver and kidney transplant. For patients with less advanced liver disease, consideration could be given to interferon therapy before proceeding with kidney transplantation to provide the opportunity for viral clearance. Kidney transplantation was previously contraindicated in people with HIV infection secondary to concerns of exacerbating an already immunologically compromised state. Recent advances in antiretroviral therapy and the ability to provide effective prophylaxis against opportunistic infections has prompted several centers to perform transplantation in people with end-stage renal disease and HIV infection. Early results suggest that progression of HIV to AIDS has not been seen following transplantation and immunosuppression, with early allograft success rates comparable to those in non-HIV-positive recipients.¹⁴ Potential patients with a previous history of tuberculosis or conversion to purified protein derivative positivity should be evaluated for active disease.

Colonoscopy, mammography, and Pap smear should be performed as dictated by age-specific standard guidelines. For most malignancies, with the exception of nonmelanoma skin cancers and early-stage renal cancers, a disease-free interval of 5 years is recommended before kidney transplantation.

For patients with congenital abnormalities as the cause of renal failure, a complete workup of the genitourinary systems is necessary, including urodynamics and voiding cystourethrograms. These studies are particularly important in children with end-stage disease resulting from posterior urethral valves, to ensure that the bladder will serve as an adequate conduit for the kidney transplant. For patients with severe reflux disease and chronic pyelonephritis, native nephroureterectomy may be required to prevent posttransplant infection secondary to chronic reflux into the native ureters. For patients with inadequate bladder capacity and function, pretransplant reconstructive procedures such as ileal augmentation or ileal conduits may be required.

For patients with suspected clotting disorders based on a previous history of thromboembolic events (frequent clotting problems with dialysis access) or diseases associated with an increased frequency of clotting disorders (i.e., lupus), a hematologic workup is necessary to determine the necessity for anticoagulation at the time of the transplant. This workup should include a determination of serum levels of protein C, protein S, anticardiolipin antibody, factor V Leiden, antithrombin III levels, and the G20210 A prothrombin gene mutation.

Living Donor Nephrectomy: Open and Laparoscopic

A living kidney donor operation is a unique surgical procedure for two reasons. First, the donor has no medical reason to be in the operating room, and the process is driven only by his or her willingness to help another person with the gift of donation. Second, the removed tissue must be in perfect condition because it will be reimplanted into the recipient. These two features, therefore, necessitate that the donor operation is done safely and done well. The original donor operation was done through a generous flank incision, allowing for good exposure and careful dissection of the renal vessels. Unfortunately, this flank approach generally left a large incision, with its accompanying morbidity, pain, and sometimes adverse cosmetic result. The development of the laparoscopic procedure to remove kidneys has revolutionized the field, although its initial introduction was met with trepidation because of concerns over donor safety. With the explosive growth and dissemination of this procedure, it has now become the standard for donor nephrectomy.

The procedure is most commonly done through a transperitoneal approach, although some surgeons prefer to remain retroperitoneal. Once the operative space is expanded with carbon dioxide gas and the scope is inserted, two to three additional ports are placed to allow for the passage of instruments to dissect the kidney (Fig. 35.2). Some centers also favor the use of a gastight “hand-port,” which allows placement of the surgeon’s hand in the operative space to assist in exposure and to have available if sudden bleeding is encountered. Once the kidney vessels are transected and the vessel stumps are controlled by laparoscopic staples, the kidney can be removed through a 2- to 3-inch incision, which can be placed in a position that leaves minimal scarring and avoids cutting muscle tissue. Most commonly this is via a Pfannenstiel incision, and recently the use of natural orifice approaches (NOTES) has been described. Donors who undergo the laparoscopic procedure typically have reduced pain medicine requirements, have a slightly shorter hospital stay, and are able to return to their usual activities sooner.^{5,6}

The safety of this relatively new procedure has been established, in addition to the demonstration that kidneys recovered through a laparoscopic approach function as well as kidneys removed in an open operation. It is important that there seems to have been an increased interest in live donation, coincident with the introduction of the laparoscopic procedure, suggesting that this procedure has removed some of the disincentives of the donation process.

Recipient Operative Procedure

- 5 The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa. Although this is a less technically demanding procedure than either liver or pancreas transplants, attention to detail is imperative to optimize immediate graft function and avoid technical complications resulting in loss of the kidney transplant.

The operation is initiated by exposure of the iliac fossa through a curvilinear incision and can be done on either the right or left side. The incision extends from 1 cm above the symphysis pubis to approximately 2 cm lateral to the anterior iliac spine (Fig. 35.3). The fascia is divided along the lateral border of the rectus sheath, and the contents of the peritoneal cavity are reflected cephalad and medially, exposing the iliac vessels in the retroperitoneum. Lymphatics overlying the iliac vessels are ligated and divided to prevent the development of lymphoceles. In males, the spermatic cord is secured with a vessel loop and can be retracted away from the operative field. In females, the round ligament is suture ligated and divided. The inferior epigastric artery and vein are typically divided to prevent potential compression of the transplanted ureter. Placement of a mechanical retractor should avoid compression of the iliac artery and vein as well as the femoral nerve to prevent neurapraxias.

The living or deceased donor kidney is inspected for the presence of multiple vessels, duplication of the urinary collecting system, and parenchymal abnormalities. The artery and vein are dissected from surrounding structures to provide the necessary length for transplantation. In the case of multiple arteries, a decision must be made as to whether to perform *ex vivo* reconstruction to achieve a single implantable conduit versus implanting the vessels separately. This decision is in part dependent on the quality of the recipient vessels and an assessment as to whether the anastomosis of multiple vessels directly into the recipient would require an unacceptable period of warm ischemia to the kidney. In general, in an adult the anastomosis of the renal artery and vein are performed in an end-to-side fashion to the external iliac vessels, although occasionally the presence of atherosclerotic disease requires transplantation to the common iliac vessels. In children who weigh less than 20 kg, or for third transplants in adults, an

FIGURE 35.2. A: The laparoscopic donor procedure is performed with the donor in a lateral position, typically using three to four ports, with extraction of the kidney through a 6- to 8-cm incision. B: Preoperative computed tomography angiogram revealing the arterial and venous anatomy. C: Intraoperative photograph of laparoscopic view of right kidney just prior to transection of the renal vein. The artery has already been divided.

intraoperative approach is used and the vascular anastomoses are frequently performed to the aorta and inferior vena cava. For kidneys from deceased donors, a Carrel patch of aorta is used to prevent stenosis and to provide a common patch for multiple arteries. Warm ischemia time should be minimized to prevent delayed graft function. Ensuring adequate intravascular volume and stable hemodynamics at the time of reperfusion is extremely important to achieve optimal function of the transplant.

The reimplantation of the ureter is most frequently performed through an extravascular technique. Following positioning of the revascularized kidney in the iliac fossa and assurance of hemostasis, the ureter is shortened to permit a tension-free anastomosis with adequate blood supply to the distal ureter. In men, the ureter is placed under the spermatic cord to prevent ureteral obstruction. The bladder is distended with an antibiotic solution to identify a suitable area for ureteral implantation on the dome of the bladder, and a

FIGURE 35.3. A: Curvilinear iliac fossa incision used for the kidney transplant recipient procedure. B: Vascular anastomoses completed between the recipient external iliac artery and vein and donor renal artery and vein. Insets: ureteral anastomosis performed using the external ureteroneocystostomy technique.

cystotomy is made at this site. An anastomosis between the mucosa of the bladder and transplanted ureter is constructed using an absorbable suture to prevent stone formation. A second layer of the bladder musculature is closed over the distal portion of the ureter to prevent reflux during micturition.

There are alternative techniques to reimplant the ureter, including the Politano-Leadbetter transvesical ureteroneocystostomy. This technique involves tunneling the ureter through the bladder wall from the inside of the bladder. This technique is still preferred by some surgeons who believe the long-term prevention of reflux is superior with the transvesicular approach. However, this technique requires a second cystotomy, and post-transplant hematuria is more common than with the extravesicular technique. A third technique for ureteral implantation in recipients with normal native ureters is uretero-ureterostomy over a double-J stent. In general, this technique is reserved as a salvage procedure for reimplantation of transplanted ureters with distal strictures secondary to ischemia. It can also be used as a primary technique if there are questions regarding the blood supply to the distal ureter at the time of transplant. This technique is preferred if the donor ureter was damaged or inadvertently stripped of its blood supply at the time of procurement but is dependent on the availability of normal native ureters to serve as an adequate conduit.

COMPLICATIONS

Early Graft Dysfunction

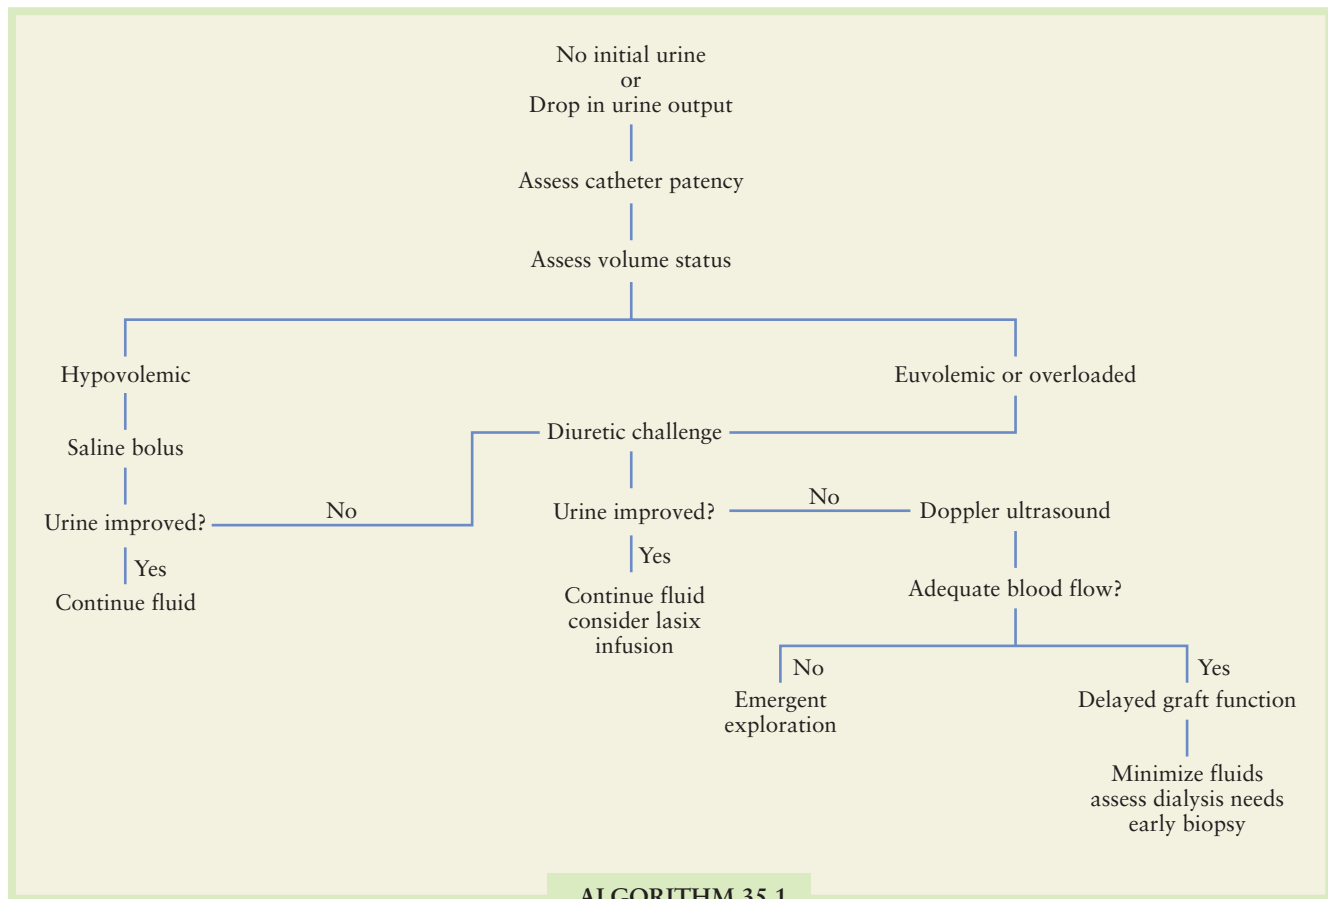

Most kidneys begin to function right after implantation, especially in the case of a living donor. When the initial function

results in only a slow drop in serum creatinine, the diagnosis of slow graft function is made. When dialysis is needed in the first week because of poor function, the diagnosis of delayed graft function is made. Delayed graft function typically occurs in 15% to 30% of deceased donor transplants. The diagnosis of slow graft function or delayed graft function is important to establish because other problems, such as rejection, vascular occlusion, or ureteral obstruction, can also result in low urine output and need for dialysis. These other causes must be eliminated before the diagnosis of slow graft function or delayed graft function can be made.

In the immediate postoperative period, careful attention to fluid status is critical. In cases of immediate graft function, fluid orders should include replacement for urine output as well as a maintenance fluid rate. This approach ensures that the patient does not become volume depleted and compromise perfusion to the new kidney. In cases of delayed graft function, fluid should be restricted and dialysis instituted when electrolyte imbalance or fluid overload are evident.

A decrease in urine output in the early postoperative period requires immediate diagnostic and therapeutic intervention. A stepwise approach to diagnosing the etiology of oliguria is shown in Algorithm 35.1. Once mechanical obstruction of the indwelling Foley catheter has been excluded by irrigation, the volume status of the patient should be assessed, preferably with a central venous pressure line or pulmonary artery catheter. Fluid replacement to restore intravascular volume should be initiated in the volume-depleted patient.

Radiologic evaluation using various imaging techniques is required if urine output remains low in the face of adequate volume status. Ultrasonography is most helpful to diagnose ureteral obstruction caused by technical complications at the

ALGORITHM 35.1. Stepwise approach to the management of decreased low urine output posttransplant.

anastomosis or fluid collections that may be obstructing the ureter by extrinsic compression. With the addition of duplex and color Doppler imaging, blood flow to the kidney can be evaluated and technical problems with the vessels can be assessed. Nuclear medicine techniques are also valuable for assessing renal function. Technetium 99m diethylenetriamine pentaacetic acid (DTPA) and iodine-131 iodohippurate (Hippuran) are the two major radionuclides used in the evaluation of renal allograft function. DTPA renal scans evaluate the vascular flow pattern of the kidney as well as the gross anatomy of the ureter and bladder. Scans are performed over 30 minutes, with uptake of contrast within 6 seconds indicating adequate flow to the graft. Peak activity in the parenchyma should be reached within 2 minutes, followed by a gradual decline in radioactivity in the renal parenchyma and an increase in radioactivity in the urinary collecting system and bladder. Iodine-131 iodohippurate scans are more sensitive in evaluating renal function. Peak activity is also reached in 2 to 4 minutes, with gradual decline over the next 30 minutes. In rejection, acute tubular necrosis and drug toxicity as well as poor uptake and poor excretion are the typical findings with a nuclear medicine scan.

If these imaging techniques do not indicate an explanation for the poor urine output, the diagnosis of delayed graft function is made. Immunosuppression can then be adjusted to minimize or avoid the calcineurin inhibitors, which can prolong the recovery from delayed graft function, and also to initiate antibody therapy to protect the kidney from rejection. The combination of delayed graft function and early rejection is clearly associated with worse outcome in the long term, and an early biopsy of the kidney that is functioning poorly is helpful to diagnose rejection and guide therapy.

Technical Complications

- 6 Most surgical complications are experienced in the immediate postoperative period. The two main types of complications can be classified as vascular and urologic.

Renal artery thrombosis is a rare complication occurring in about 1% of transplants. The risk of this complication is higher with size mismatch of donor renal artery and recipient internal iliac artery when an end-to-end anastomosis is performed, in kidneys with multiple renal arteries, in kidneys traumatized because of rough handling, and in the presence of an unidentified renal artery intimal flap. Sudden loss of urinary output, not the result of an obstructed Foley catheter or inadequate vascular volume, should necessitate a workup with duplex Doppler ultrasound. Loss of signal is indicative of no flow to the kidney. Alternatively, a nuclear medicine renal scan is informative, with lack of isotope uptake by the kidney indicating no blood flow. Prompt return to the operating room for correction of a technical problem is imperative, but often the diagnosis is not made quickly enough to salvage the kidney.

Renal artery stenosis occurs in up to 15% of transplanted kidneys. Difficult-to-control hypertension should suggest the possibility of stenosis. Diagnosis with renal duplex ultrasound followed by arteriography to better define the anatomy and degree of stenosis should be done before operative repair or angioplasty. Initial success rates for both methods are similar (75%–80%), but the restenosis rate following angioplasty is not well defined. Anastomotic strictures respond less well to angioplasty and probably should be repaired by operative intervention.

Aneurysms that occur in the renal artery are either pseudoaneurysms at the anastomotic site or mycotic aneurysms secondary to bacterial or fungal infection. A rapidly expanding, tender pulsatile mass in the region of the kidney suggests a mycotic aneurysm. Arteriography is confirmatory for diagnosis. Treatment consists of appropriate antibiotics and removal of the transplanted kidney.

FIGURE 35.4. Percutaneous nephrostogram revealing a urine leak from the ureterovesical anastomosis.

Venous complications are less frequent, with thrombosis occurring in 1% to 4% of transplants. Causative factors include intimal damage during retrieval, kinking at the iliac vein anastomosis, or pressure secondary to a lymphocele, urinoma, or hematoma. Occasionally, severe rejection can result in venous occlusion. Heparin infusion for incomplete occlusion and transplant nephrectomy for complete occlusion are the indicated therapies. Occasionally, graft salvage is possible if the diagnosis is made before progression of clot into the kidney itself. The classic sign of new hematuria may be an early hint of a renal vein problem and should lead to an ultrasound.

Urologic complications include ureteral obstruction, urinary fistula, or bladder leak. These complications all present with decreased urine output and a rise in serum creatinine. With a urine leak, pain in the region of the transplant may be severe. Mechanical obstruction of the Foley catheter must first be eliminated. Ureteral obstruction occurs in 1% to 9% of transplants, and diagnosis can be made with ultrasonography demonstrating hydronephrosis. A leak is usually diagnosed with a nuclear medicine renal scan. Further definition of a leak or stricture can be obtained via an antegrade pyelogram (Fig. 35.4). Early obstruction of the transplant ureter at the site of the bladder anastomosis may respond to internal stenting. Late strictures usually require reoperation, and urine and blood polymerase chain reaction for the polyoma virus should be done in that circumstance, because polyoma viral infection can lead to ureteral stricture. The surgical correction of a ureteral stricture may require reimplantation of the ureter into the bladder, the creation of a Boari flap, or the use of the recipient's native ureter for a ureteroureterostomy (Fig. 35.5).

IMMUNOSUPPRESSION, REJECTION, AND IMMUNOSUPPRESSIVE COMPLICATIONS

Immunosuppression

Major advances in the ability to block immune-mediated destruction of the kidney have taken place in the past few years, resulting in a significant decrease in the incidence of acute rejection and improvement in long-term allograft survival rates.¹³ This advance is the result of numerous agents that have been added during the past decade to the

FIGURE 35.5. A: Reconstruction of a stenotic donor ureter, showing resection of the stenotic segment and mobilization of the bladder. B to D: A Boari flap is constructed from a tabularized segment of bladder wall and anastomosed end-to-end to the proximal donor ureter.

immunosuppressive armamentarium of prednisone, azathioprine, and cyclosporine A. These agents include tacrolimus, mycophenolate mofetil, sirolimus, anti-interleukin-2 receptor blockers, antithymocyte globulin (a polyclonal anti-T-cell agent), rituximab (an anti-CD20 monoclonal agent), and most recently costimulatory blockade with CTLA4-Ig. The addition of various newer drugs targeting different pathways in the alloimmune cascade has permitted the development of regimens that are less dependent on the calcineurin inhibitors or prednisone.¹⁵

Newer strategies in the immunosuppressive pipeline are targeted to block: costimulatory pathways; signaling pathways that activate T cells and T-cell proliferation; and trafficking and recruitment of immune cells. The most promising biologic agents targeted to block the costimulatory pathways include a second-generation CTLA4Ig (LEA29Y), a humanized anti-CD11-a (anti-LFA1), and a humanized anti-B7.1/B7.2. Promising agents designed to block T-cell activation and proliferation are the inhibitors of the Janus protein tyrosine kinase (JAK3) and the leflunomide analog FK778. Finally, drugs to block the trafficking and recruitment of immune cells are antagonists against the chemokine receptors CCR1, CXCR3, and CCR5. The chemokine antagonists have been effective in experimental transplantation and will likely be transitioned to clinical trials in the near future.¹⁶

Rejection

7 Hyperacute rejection is extremely rare and is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney, whereas classic cell-mediated rejection typically does not occur until 1 to 2 weeks after the transplant. In hyperacute rejection, the anti-HLA antigens bind to the vascular endothelium of the kidney transplant, resulting in activation of the complement cascade and rapid graft thrombosis. The kidney appears blue-black with poor tissue turgor despite adequate blood flow. The characteristic histologic appearance includes the triad of polymorphonuclear leukocytes in the glomerular capillary loops, fibrin deposition, and platelet thrombi. The kidney cannot be salvaged, and a transplant nephrectomy is necessary. The presence of anti-HLA antibodies should be detected in the pretransplant cross-match, and with the sensitivity of current immunologic assays, hyperacute rejection is usually a result of technical or clerical errors in the cross-match procedure. A more common and less intense form of humoral rejection occurring within a few days of transplantation is a result of reactivation of memory B cells following reexposure to alloantigen. The histologic findings are defined by positive C4d staining on vascular endothelium, although lymphocytic infiltrates consistent with classic cell-mediated rejection can be

present. Treatment of this aggressive rejection can include plasmapheresis, the anti B-cell agent rituximab (anti-CD20 monoclonal antibody), and polyclonal antilymphocyte preparations (antithymocyte globulin).

- 8 Classic acute cell-mediated rejection typically occurs between 1 week and 3 months following transplantation. Most patients with rejection episodes present with decreasing urine volumes and increases in serum creatinine values. Low-grade fever and allograft tenderness may be present, but significant physical symptoms frequently are absent. Immediate workup of increasing serum creatinine should be initiated, beginning with an ultrasound to rule out ureteral obstruction or technical vascular complications as the cause of the deteriorating function. Similarly, toxicity from calcineurin inhibitors needs to be determined by checking drug levels. A percutaneous kidney biopsy is performed to confirm rejection. The severity of the rejection episode is based on the presence of lymphocytes in renal tubules (tubulitis) and vascular endothelium (vasculitis). Mild rejection is generally treated with pulse corticosteroids and maximizing the maintenance immunosuppression to ensure therapeutic levels of calcineurin inhibitors. More severe rejection with both tubulitis and vasculitis, as well as steroid-resistant rejection, is treated with antilymphocyte antibody preparations, most frequently muromonab-CD3 (a monoclonal agent directed against the CD3 receptor) or rabbit polyclonal antilymphocyte preparations. If the rejection episode occurred while the patients had therapeutic drug levels, maintenance therapy is frequently altered following the antibody therapy. For example, if maintenance therapy consisted of cyclosporine A, the calcineurin inhibitor could be switched to tacrolimus. Other potential strategies include the addition of sirolimus to the immunosuppressive regimen, particularly for cases where there is evidence of calcineurin inhibitor toxicity on biopsy.

Each rejection episode takes a toll on long-term function of the kidney transplant. Even well-controlled acute rejection episodes initiate a cascade of events leading to interstitial fibrosis and proliferative changes affecting the vascular endothelium. These histologic and progressive degenerative changes are classified as chronic rejection or chronic allograft nephropathy. These changes lead to loss of graft function over the course of months to several years. Current strategies minimizing calcineurin inhibitor nephrotoxicity are being used to prolong function in kidneys with these chronic changes and involve the addition of sirolimus to replace the calcineurin inhibitors. It remains unclear whether the marked decrease in acute rejection episodes, from greater than 50% to less than 20% observed in the past 5 years, will translate to better long-term function of transplants. Nonetheless, it is evident that immunosuppression strategies minimizing prednisone and calcineurin inhibitors are providing safer and more effective immunosuppression for kidney transplant recipients while decreasing long-term toxicities associated with immunosuppression.

Immunosuppressive Complications

It would be naïve to assume that the intensification of immunosuppressive regimens resulting in decreased acute and chronic rejection rates can be accomplished without sequelae. Infections and malignancy remain significant complications associated with long-term immunosuppression and are the driving force for drug-minimization strategies. Early infections during the perioperative period are commonly iatrogenic and involve bladder infections or intravenous catheter use. Higher doses of immunosuppressive drugs used in the early postoperative period predispose patients to these infections and emphasize the importance of maintaining sterility during Foley catheter placement and insertion of intravenous catheters. Pneumonia related to mechanical ventilation and poor postop-

erative inspiratory effort can occur in the early postoperative period, and early incentive spirometry should be encouraged to decrease the potential for this infection. Wound infections are relatively uncommon, although diabetes and obesity are both associated with a much higher incidence of wound complications. Weight reduction to achieve a body mass index of less than 35 is strongly recommended to facilitate the operative procedure and minimize the risks of wound complications, particularly in the recipient with diabetes mellitus.

Cytomegalovirus (CMV), a herpesvirus, remains a problematic infection in the immunosuppressed patient and can become symptomatic 1 to 2 months following the transplant. CMV-seronegative patients who receive a kidney from a CMV-seropositive donor are at the highest risk for infection, although prophylaxis with acyclovir or ganciclovir is generally provided for all recipients for a period of 3 to 6 months following the transplant. Despite prophylaxis, activation of CMV can occur, accompanied by fever, malaise, pneumonia, gastrointestinal distress, or dysfunction of the kidney transplant. The effective treatment of blood- or tissue-invasive CMV has been one of the major advances in the management of kidney transplant patients within the past decade. What was a life-threatening disease in the early era of solid organ transplantation can today be effectively managed with oral antibiotics.

Prophylaxis against *Candida albicans* with fluconazole and *Pneumocystis carinii* with trimethoprim-sulfamethoxazole is also part of most management strategies posttransplant. Other potentially life-threatening opportunistic organisms that can affect the chronically immunosuppressed transplant recipient include *Aspergillus*, *Cryptococcus*, *Listeria*, *Nocardia*, and *Mycobacterium*.

More potent immunosuppression regimens used in the current era have been associated with the emergence of polyoma or BK virus, a previously rare infection that may cause graft loss in up to 5% of infected patients. Reduction in immunosuppression is necessary to prevent progression of viral tubulitis. There has been some experience with the use of leflunomide, ironically an immunosuppressive agent, but with an active metabolite, A77 1726, that has substantial antiviral activity in vitro and in animals. Another potential medication, cidofovir, is a nucleotide analogue that inhibits viral DNA polymerase but unfortunately is also nephrotoxic, and its in vivo efficacy has not been proved. Probably the best method to prevent graft loss due to polyoma is the use of monitoring of urine and serum levels of BK virus, with lowering of immunosuppression when early evidence of polyoma is detected.

Patients with a previous history of active tuberculosis or conversion to purified protein derivative (PPD) positivity should receive appropriate prophylaxis for 6 months to 1 year following the transplant procedure.

More potent immunosuppression regimens will also have an impact on the development of neoplasms following transplantation.¹⁷ Skin cancers are the most common malignancy following transplantation, with more than 90% being squamous or basal cell cancers. The incidence of skin cancers is staggering, with 50% or more of white recipients ultimately developing lesions. The immunosuppressed patient also has a higher incidence of nodal spread, and educating the patient about the importance of avoiding direct sun exposure is essential. Other malignancies that have a particularly high incidence in transplant recipients include non-Hodgkin lymphomas and carcinomas of the anogenital areas. The etiology of anogenital carcinoma is related to the presence of human papilloma virus.

Posttransplant lymphoproliferative disease is the second most common form of malignancy in transplant recipients and is associated with Epstein-Barr virus. These lymphoproliferative syndromes present as a spectrum of pathology, extending from polyclonal lymphoproliferation to monoclonal B-cell lymphomas. Polyclonal disease has been managed by decreasing or withdrawing immunosuppression, whereas progression

FIGURE 35.6. Comparison of graft survival and graft half-life ($t_{1/2}$) in 1992 and 2002 for different donor types (age >60 years in 1992 group, age >50 years with hypertension, elevated creatinine, or donor death from cerebrovascular accident in 2002 group). There has been an improvement in survival for all donor types, with the best long-term results with living donor kidneys. ECD, extended criteria donor; LD, living donor; SCD, standard deceased donor.

to monoclonal lymphomas has required chemotherapy. CD20-positive lymphomas have been successfully managed with rituximab, an anti-CD20 antibody, with no significant side effects.

CURRENT RESULTS AND FUTURE TRENDS

Over the past three decades, progressive improvement has been made in patient and graft survival, independent of donor source. This progression is best shown in Figure 35.6 for the period of time spanning 1992 to 2002. Overall graft survival, as well as the half-life of the graft, improved incrementally for live donor transplants, standard deceased donor transplants, and even deceased donor transplants using suboptimal or extended criteria donors.¹³ This change is related to improved organ preservation, perfected operative technique, and most important, improved immunosuppressive agents. Current 1-year actuarial graft survival rates for living and deceased donor transplants are 94.8% and 88.9%, respectively.¹⁸ These remarkable 1-year results continue to be overshadowed by the specter of late graft loss due to chronic rejection. This problem remains unsolved in renal transplantation, and future improvement in long-term survival will be achieved only when the mechanisms of this process are understood.

The exponential growth in waiting lists compounded by the ongoing critical shortage of organs will continue to stimulate creative means of increasing both the living and deceased donor pools. Expansion in the number and types of immuno-

suppressive agents has resulted in marked decreases in the incidence of acute rejection, which it is hoped will translate to prolongation in the long-term function of kidney transplants. Newer strategies in immunosuppressive regimens that minimize nephrotoxic cyclosporine and tacrolimus by adding non-nephrotoxic agents will also benefit the long-term function of transplanted kidneys. The effect of ischemia-reperfusion injury on both early and late graft function, as well as its impact on the development of chronic rejection and transplant glomerulopathy, is an area of active research, and potential therapeutic interventions to minimize this injury are being evaluated. The induction of tolerance to foreign antigen remains the “holy grail” of transplantation. A paucity of tolerizing regimens have been applied clinically, although the use of donor bone marrow or stem cells will likely have a future role in achieving the elusive goal of transplantation tolerance.

CHAPTER 36 ■ HEPATIC TRANSPLANTATION

THEODORE H. WELLING AND SHAWN J. PELLETIER

KEY POINTS

- 1 The main indication for liver transplantation is end-stage liver disease, defined as the clinical scenario in which a pathologic process or multiple processes have resulted in a damaged liver that has minimal function and no potential for recovery.
- 2 The Organ Procurement and Transplantation Network uses the Model of End-stage Liver Disease (MELD) score as a method of prioritizing liver transplant recipients. The MELD score is an integer value based on three objective laboratory studies: creatinine, bilirubin, and the international normalized ratio.
- 3 The degree of preoperative debilitation and the complexity of the operative procedure make complications following hepatic transplantation very common.
- 4 Approximately 2% to 10% of transplanted livers function so poorly in the immediate postoperative period that death is likely in the absence of retransplantation, a condition referred to as primary nonfunction of the allograft.
- 5 Liver transplant recipients require less immune suppression than patients with other types of allografts, such as heart, lung, and kidney recipients.
- 6 Typical acute rejection in liver transplant recipients is usually cell mediated.
- 7 Chronic rejection is characterized by relentless immune attack on small bile ducts. Histologically, small bile ducts are obliterated or completely absent, termed *vanishing bile duct syndrome*.
- 8 The patient survival rate following liver transplantation in the United States at 1 year is more than 85% for adults and nearly 90% for children.

Liver transplantation has evolved over the past four decades to be the standard treatment for patients with a variety of acute and chronic liver diseases. The first successful liver transplant was performed on a moribund child with a hepatoma by Dr. Thomas Starzl at the University of Colorado in 1967.¹ This child lived more than a year before succumbing to recurrent tumor. Over the next 12 years, liver transplants continued to be performed at a modest rate. Despite 1-year survival rates of less than 50%, it was clear that some patients benefited from the procedure.

In 1979, cyclosporine was introduced into clinical organ transplantation by Sir Roy Calne.² Almost immediately, 1-year patient survival rates jumped to over 70%. As a result, liver transplantation programs began to appear worldwide. Today more than 10,000 liver transplants are performed annually in the United States, and survival rates exceed 85% at 1 year and 70% at 5 years, primarily varying on liver disease indication.^{3,4}

The clinical expanse of liver transplantation is now primarily limited by the availability of suitable donor organs. Every year more patients are listed for liver transplantation than receive transplants. In the future it is likely that this problem will worsen because of the large number of individuals with chronic hepatitis C infection, a significant portion of whom will eventually develop cirrhosis and hepatocellular carcinoma (HCC), and the expanding numbers of patients with either HCC or nonalcoholic steatohepatitis (NASH).⁵ Attention continues to be focused on methods to increase the available supply of livers for transplantation. Notable efforts to improve the supply of available organs include the work by the Department of Health and Human Services, which recently took up the cause of organ donation vigorously. This effort, termed the Organ Donation Breakthrough Collaborative,⁶ focused on improving the success rate of organ donation efforts at the hospitals that have most potential organ donors nationwide. The Centers for Medicare and Medicaid Services also joined the effort by declaring specific Conditions of Participation for all hospitals that treat Medicare patients in the United States.⁷ This effort focused on encouraging methods of approaching donor families that have been shown to be optimally effective.

Many other methods to increase the number of donor livers are currently being practiced. These methods include the utilization of older liver donors and steatotic donor livers, the development of techniques to allow a single liver graft to be split into two grafts, and the utilization of liver grafts from donors that die of cardiac death (DCD). Recently, many centers have continued the development of safe surgical techniques that allow healthy, living volunteers to donate a segment of their liver to a recipient in need of a liver transplant.^{8,9}

GENERAL INDICATIONS FOR HEPATIC TRANSPLANTATION

- 1 The most common indication for liver transplantation is end-stage liver disease. The term *end stage* refers to the clinical scenario in which a pathologic process or multiple processes have resulted in a damaged liver that has minimal function and no potential for recovery. The diagnosis of end-stage liver disease is made primarily on the basis of clinical findings. Additional information about the etiology of the liver disease and thus its natural history can often be obtained by supplementary investigations including serologic studies and histologic examination of a liver biopsy specimen. It is important that potential liver transplant recipients are evaluated by a specialist with expertise in end-stage liver disease, because many other diseases may present similar clinical pictures.

The severity of liver disease in an individual is highly variable, from mild cirrhosis and no symptoms to severe decompensation resulting in deterioration of mental status and frank renal failure. The rate of progression of liver disease from a functional state to invalidism to death is variable and may be rapid or may take several years. The challenge facing liver transplant professionals is to identify patients who will benefit from transplantation. Hepatic transplantation may result in wonderful and dramatic results, but at the same time it is always a high-risk procedure. In situations in which patients enjoy full performance status, and are only

TABLE 36.1**FORMULAS TO CALCULATE MELD AND PELD SCORES**

$$\text{MELD score} = 0.957 \times \text{Log}_e (\text{Creatinine [mg/dL]}) + 0.378 \times \text{Log}_e (\text{Total bilirubin [mg/mL]}) + 1.120 \times \text{Log}_e (\text{INR}) + 0.643$$

$$\text{PELD score} = 0.436 (\text{Age younger than 1 year} = 1, \text{Older} = 0) - 0.687 \times \text{Log}_e (\text{Albumin [g/dL]}) + 0.480 \times \text{Log}_e (\text{Total bilirubin [mg/mL]}) + 1.857 \times \text{Log}_e (\text{INR}) + 0.667 (\text{Growth failure} = 1)$$

INR, international normalized ratio; MELD, Model of End-stage Liver Disease; PELD, Pediatric End-stage Liver Disease.

minimally symptomatic, transplantation is an inappropriate therapeutic measure. A liver transplant is a major surgical procedure on a profoundly ill individual with unavoidable risk that also requires chronic, lifelong immunosuppression. Despite advances in immunosuppressive medications developed over the past four decades, immunosuppression remains a treatment that induces a state of vulnerability in the recipient by virtue of the fact that the recipient's natural resistance to infection and malignancy is compromised. It is thus critical that patients be carefully selected as to who will benefit from the procedure.

2 How is it possible to properly select patients and properly time transplantation so that the benefit of transplantation is assured? In 2002, the Organ Procurement and Transplantation Network began using the Model of End-stage Liver Disease (MELD)¹⁰ score as a method of prioritizing liver transplant recipients. The MELD score is an integer value based on three objective laboratory studies: creatinine, bilirubin, and the international normalized ratio (INR) (Table 36.1). This has been adapted to pediatric patients as well (Pediatric End-stage Liver Disease [PELD]) utilizing the variables in MELD along with albumin instead of creatinine and including age as well as the presence of growth failure (Table 36.1). Analysis done by the Scientific Registry of Transplant Recipients (SRTR) has shown that patients with MELD scores of less than 15 have a mortality rate on the waiting list that is less than the mortality of the transplant procedure in the same population.¹¹ This suggests that patients with a MELD score of less than 15 do not receive an absolute survival benefit from transplantation, whereas patients with higher MELD scores have the potential to receive a survival benefit with liver transplantation. In other words, there is no evidence that patients who are too ill from liver disease to benefit from liver transplantation are being transplanted, but patients who have stable, mild liver disease should not receive a transplant until their disease has progressed to a more severe state.

Surprisingly, MELD more accurately predicts mortality than clinical factors that were previously thought to be ominous signs of reduced (6 months or less) survival. Such factors, including the presence of ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, and variceal hemorrhage, do not add to the predictive value of MELD.¹⁰ This finding may be related to the difficult nature of accurately quantifying clinical variables in registry databases or to the fact that MELD is such an accurate way of measuring functional hepatic capacity that no additional clinical variables are more relevant.

As will be discussed later, the transplant community has agreed upon certain exceptions to the MELD score for patients with chronic liver disease. It is generally supported that patients with diseases such as HCC, hepatopulmonary syndrome (HPS), primary oxaluria, and familial amyloidosis benefit from additional MELD points by regional review boards. Other diseases or complications such as portal vein thrombosis or portal pulmonary hypertension (PPHTN) remain less clear and are handled on a case-by-case basis.¹²

TABLE 36.2**URGENT LISTING CRITERIA FOR LIVER TRANSPLANTATION**

Status 1A	<i>Fulminant hepatic failure</i> (encephalopathy within 8 wk of liver disease and ICU status with ventilator dependence, renal replacement therapy, INR >2.0, or acute Wilson disease) <i>Hepatic artery thrombosis of liver transplant</i> (AST >3,000 U/mL and INR >2.5 or acidosis within 7 d) <i>Primary nonfunction of liver transplant</i> (AST >3,000 U/mL and INR >2.5 or acidosis within 7 d) <i>Anhepatic state</i> (graft removal for any reason)
Status 1B	Age <18, chronic liver disease in ICU with MELD/PELD >25 plus one of following: ventilator dependence, GI bleeding, renal replacement therapy, Glasgow Coma Score <10

AST, aspartate aminotransferase; GI, gastrointestinal; ICU, intensive care unit; INR, international normalized ratio; MELD, Model of End-stage Liver Disease; PELD, Pediatric End-stage Liver Disease.

The improved ability to predict mortality for patients with liver failure allowed the development of national allocation policies that direct livers to those patients who will benefit. Importantly, the implementation of the MELD system of allocation for livers from deceased donors has been associated with a decrease in the death rate on the waiting list.¹³ Further refinements of our understanding will undoubtedly occur as improved long-term follow-up data on waiting list mortality become available and as quality-of-life considerations are added to the analysis.

These considerations apply to the chronic forms of liver failure, but not to the important emergency decisions about transplantation that must be made when a patient presents with fulminant hepatic failure (FHF), which is defined as the progression from good health to liver failure with hepatic encephalopathy within 8 weeks. Without transplantation, the mortality rate for fulminant hepatic failure is approximately 75%.¹⁴ Death often occurs rapidly once patients progress to stage II (confusion), stage III (stuporous), or stage IV (unresponsive) hepatic encephalopathy. In these cases, the decision to perform transplantation is based on clinical grounds. Current liver transplant allocation policy allows for the rapid transplantation of patients with fulminant hepatic failure. These patients can be listed as status 1A (Table 36.2), which gives them higher priority for available livers than patients with chronic liver disease who are prioritized based on MELD score.

Contraindications to Liver Transplantation

The number of absolute contraindications to hepatic transplantation has steadily decreased during the past several years as experience with the procedure has increased. Many clinical situations once considered to be absolute contraindications for transplantation are now either no longer considered to be contraindications or to be only relative contraindications. A thrombosed portal vein is no longer a contraindication to transplantation because techniques have been devised to effectively deal with this condition (see later).¹⁵ The presence of juvenile-onset diabetes mellitus formerly precluded transplantation. In current practice, this is not usually the case, depending on the patient's physiologic status at the time of evaluation. Similarly, advanced age causes concern, but in most

centers the physiologic state of the patient is a more important consideration than the chronologic age.

The inability to withstand the operative procedure, usually for cardiovascular or pulmonary reasons, is considered to be a contraindication to liver transplantation. Specific examples include patients with depressed ejection fraction secondary to ischemic cardiomyopathy, significant pulmonary hypertension, and significant chronic obstructive pulmonary disease. Cardiac disease that is not amenable to percutaneous therapy poses a particular problem because these patients are frequently unable to withstand a corrective cardiac procedure because of their severe liver disease. In highly selected patients it may be possible to perform combined heart and liver transplantation or combined lung and liver transplantation.

Recent intracranial hemorrhage is almost always a contraindication because during the liver transplant procedure, coagulopathy is often present along with significant alterations in arterial blood pressure. The risk of a catastrophic exacerbation of intracranial bleeding during a transplant is therefore high in this setting. However, the meaning of “recent” is not defined in either the transplant or the neurosurgical literature. Profound, irreversible neurologic impairment is also considered to be a contraindication, but mild mental retardation is not necessarily problematic as long as a social support network exists to ensure compliance with posttransplant regimens. Active substance abuse remains a contraindication, as is the lack of the necessary social support network.

Human immunodeficiency virus (HIV) infection, long considered a contraindication, is no longer an absolute exclusion due to the development of highly effective antiretroviral therapies.^{16,17} Active sepsis or untreated infection and active extrahepatic malignancy continue to be contraindications.

Although renal insufficiency increases the risk of liver transplantation, it is not a contraindication. Patients who have hepatorenal syndrome (HRS) frequently experience recovery of renal function following liver transplantation. However, patients who have longstanding hepatorenal failure and patients with known renal parenchymal disease requiring renal replacement therapy are often best served by combined liver/kidney transplantation.

DISEASE-SPECIFIC INDICATIONS AND OUTCOMES

While the MELD score assessment plays a critical role in evaluating and listing patients who might benefit from liver transplantation, patients who develop liver disease-specific complications, regardless of MELD, are also appropriate to consider for liver transplantation. Some of these complications along with other liver-specific metabolic diseases are listed in Table 36.3. Hepatitis C is the most common disease for which liver transplantation is currently performed in the United States (33%) (Fig. 36.1). Alcoholic liver disease, NASH, and cholestatic liver diseases are the next most common ranging from 10% to 14% of cases. However, this trend is believed to be changing with a greater proportion of liver transplants being performed for NASH (Fig. 36.2).⁵ Outcomes following liver transplantation are best for pediatric patients with biliary atresia, while patients with cholestatic liver diseases experience the best survival among adults (Fig. 36.3). Patients with hepatitis C or HCC experience worse survival secondary to disease recurrence. Disease-specific indications, outcomes, and considerations will be discussed in the following sections.

Alcoholic Liver Disease

Excessive alcohol consumption can lead to several hepatic abnormalities, ranging from alcoholic hepatitis to steatosis,

TABLE 36.3

LIVER DISEASE COMPLICATIONS AND LIVER-SPECIFIC METABOLIC DISEASES

Complications:

- Ascites
- Encephalopathy
- Refractory variceal hemorrhage or portal gastropathy
- Hepatocellular carcinoma
- Hepatopulmonary syndrome (HPS)
- Portopulmonary hypertension (PPHTN)
- Fulminant hepatic failure (FHF)

Metabolic diseases:

- Wilson disease
- α_1 -Antitrypsin disease
- Familial amyloidosis
- Urea cycle enzyme deficiencies
- Glycogen storage disease
- Tyrosemia
- Primary oxaluria

hepatic fibrosis, and cirrhosis. Alcoholic liver disease was once thought to occur only in individuals who consumed large quantities of alcohol over long periods of time. It has recently become recognized that even moderate amounts of alcohol consumption can induce liver injury, suggesting that hereditary and/or environmental factors are probably important. Hepatitis C viral infection, found in 15% to 25% of patients with alcoholic liver disease, appears to exacerbate alcohol-induced liver injury and vice versa.

When liver transplantation emerged as a standard therapy for end-stage liver disease in the 1980s, intense debates occurred surrounding the issue of offering liver transplantation. There were two broad areas of concern. First, many were skeptical that patients with a history of longstanding alcoholism would be able to successfully comply with the rigorous long-term medical treatment required of patients who receive lifelong immunosuppression. On a broader level, concern was expressed that scarce societal resources should not be used to treat patients with “self-induced” diseases. With more experience in this area, it has been recognized that the incidence of recidivism after transplantation is low, and both short- and long-term results in this category are as good as for non-alcohol-related

FIGURE 36.1. Percentage of liver transplants for each etiology. (Reproduced with permission from O’Leary JG, Lepe R, Davis GL. Indications for liver transplantation. *Gastroenterology* 2008;134:1764–1776.)

categories. It has also become understood that determining worthiness for receiving a lifesaving organ by making a judgment about past behavior is neither ethical nor possible.

Today, the same methods of determining suitability for transplantation are used for patients with alcoholic liver disease as with other diagnoses with one proviso. Unlike other disorders that tend to be universally progressive, alcohol-induced liver injury frequently regresses following cessation of alcohol consumption as long as cirrhosis is not yet present. Patients with a history of recent alcohol abuse should therefore be observed for a minimum of 6 months to ensure that their

hepatic dysfunction is not reversible. In addition, all patients with a history of substance abuse must be evaluated by individuals with expertise in addiction and found to have good insight into their past self-destructive behavior and a stable social support network for the posttransplant phase.

Viral Hepatitis

Most patients who become infected with hepatitis B develop an immunologic response to the virus that results in complete

FIGURE 36.3. Disease-specific survival following liver transplantation. (Reproduced with permission from Roberts MS, Angus DC, Bryce CL, et al. Survival after liver transplantation in the United States: a disease-specific analysis of the UNOS database. *Liver Transpl* 2004;10:886–897.)

viral clearance. Patients who do not clear the hepatitis viral antigen may persist as carriers or may develop chronic hepatitis, which progresses to fibrosis and cirrhosis. In the 1980s, transplantation for hepatitis B was associated with universal recurrence of viral infection posttransplant and survival rates were poor. Fortunately, transplantation for this indication was revolutionized by the development of effective posttransplant prophylaxis using long-term, high-dose, hepatitis B immune globulin and the nucleoside inhibitors lamivudine or entecavir.^{18,19} Today, outcomes for transplantation for hepatitis B–induced liver failure, while varying based on genotype, are equivalent to or better than those for other conditions.²⁰

Hepatitis C has become the most common etiology among patients receiving liver transplants.⁵ Antiviral therapy using pegylated interferon and ribavirin for early hepatitis C infection has been demonstrated to have clinically important responses seen in over half of patients treated. However, complete clearance of hepatitis C from serum can only be achieved in a minority of patients, which is largely related to viral genotype and whether significant toxicities to therapy develop.^{21,22}

Following liver transplantation, recurrence of hepatitis C in the transplanted liver occurs universally unless the virus was eradicated pretransplant with therapy.²³ Although some patients experience an indolent course, most patients experience a more rapid progression to liver failure once cirrhosis has developed posttransplant. These patients can progress to end-stage liver failure within 6 months.²⁴ Short-term results of transplantation for this disease are comparable to those for the other noninfectious conditions. However, approximately 25% of patients develop recurrent cirrhosis within 5 years posttransplant, and long-term survival is less likely compared with patients who do not have hepatitis C infection. Use of livers from donors of increased age is thought to contribute to poorer results in hepatitis C patients.²⁵ Treatment of recurrent hepatitis C posttransplant is often attempted with some survival benefit, but many patients are unable to tolerate therapy or fail to respond.^{24,26} Despite recurrence, transplantation appears to provide a substantial and worthwhile survival benefit to most patients with hepatitis C.

Hepatocellular Carcinoma and Other Hepatic Malignancies

Cirrhosis is a major risk factor for the development of HCC, and the majority of HCCs develop in patients who have cirrhosis. Curative resection is unsafe in the setting of advanced cirrhosis, and it does not eliminate the high likelihood of recurrent malignancy. Because most patients with HCC die of liver failure, rather than metastatic disease, it was reasoned that transplantation would be potentially curative. This approach yielded poor survival rates, and during the early 1990s primary hepatic malignancy was considered a contraindication to liver transplantation by many centers. This circumstance changed when Mazzaferro et al. reported an 85% 4-year survival rate for patients who had cirrhosis and either stage I or stage II HCC (Table 36.4).²⁷ Transplantation is now considered standard therapy for HCC and cirrhosis if there is no evidence of extrahepatic disease or vascular invasion and if the tumor burden does not exceed stage II (single tumor <5 cm in diameter, or two to three tumors, none >3 cm in diameter). While some advocate transplantation of patients with larger tumors,^{28,29} this practice is still controversial due to concerns of overall lower disease-free survival. Transplantation is clearly not beneficial in the presence of known positive nodal or distant metastases (stage IV disease). To create relative equality for a scarce resource, MELD allocation points are standardly allocated to HCC patients meeting the Milan criteria so as to minimize waitlist dropouts due to disease progression and at the same time not overutilize donor livers from the

TABLE 36.4

TNM CLASSIFICATION AND STAGING OF HEPATOCELLULAR CARCINOMA

CLASSIFICATION

T1	One nodule ≤1.9 cm
T2	One nodule 2.0–5.0 cm; two or three nodules, all <3.0 cm
T3	One nodule >5.0 cm; two or three nodules, at least one >3.0 cm
T4a	Four or more nodules, any size
T4b	T2, T3, or T4a plus gross intrahepatic portal or hepatic vein involvement on imaging
N0	No evidence of regional nodal involvement
N1	Regional (porta hepatitis) nodal involvement
M0	No evidence of metastatic disease
M1	Evidence of metastatic disease

remainder of the recipient candidate pool. However, in the latest review of outcomes of liver transplantation as reported by the SRTR,⁴ the adjusted 3-year survival rate for HCC patients was 74% and was statistically lower than non-HCC recipients (81%) during the MELD era, suggesting that the allocation policy may need further refinements.

Other primary tumors of the liver include hepatoblastoma, cholangiocarcinoma, and primary sarcoma. Hepatoblastoma occurs primarily in children with resection or transplantation being used as potential curative options.³⁰ Transplantation is utilized for patients who are unresectable because of bilobar disease or hilar location. Hepatoblastoma can respond partially to chemotherapy, but complete and sustained tumor regression is uncommon. Patients are often treated with chemotherapy until the time of transplantation to prevent extrahepatic growth prior to the definitive treatment. Hepatoblastoma is relatively unique among liver tumors in that long-term survival has been reported even in children who have had distant metastatic spread.

Cholangiocarcinoma has historically been considered a contraindication to transplantation because 5-year survival rates have been reported at less than 20%. Recently, success similar to other recipients has been reported for patients who have limited disease (<2.5 cm, no lymph node disease) and have received neoadjuvant therapies. However, more investigations are required as transplantation following this regimen has been associated with increased vascular complications.³¹

Although there are anecdotal reports of long-term survival following transplantation for primary sarcoma of the liver, the majority of experiences indicate that transplantation is not a curative therapy for this condition. Liver transplantation is generally not appropriate for patients who have secondary (metastatic) hepatic malignancy, because long-term survival rates are very poor due in part to the observation that immunosuppression promotes tumor growth. The possible exception to this rule is patients who have metastatic carcinoid that is limited to the liver. This tumor grows very slowly and local cure of the primary tumor is frequently possible. A subset of patients who have a period of years without evidence of

tumor growth anywhere else but in the liver will have long-term disease-free survival following liver transplantation.³²

Nonalcoholic Fatty Liver Disease

NASH may be the most common liver disease in the United States. It has a high incidence in obese patients and those with adult-onset diabetes mellitus. The disease resembles alcoholic liver disease, but patients do not report a significant history of alcohol use. The degree of hepatic injury varies from benign elevations of serum hepatic transaminases in association with hepatic steatosis or steatohepatitis to fibrosis and cirrhosis. A majority of patients previously classified as having cryptogenic cirrhosis probably have longstanding steatohepatitis. It is estimated that at least two thirds of the obese population in the United States have hepatic steatosis and close to one fifth have steatohepatitis.³³ Patients who develop cirrhosis and progress to end-stage liver disease are appropriate candidates for liver transplantation. Recurrence of steatohepatitis leading to graft dysfunction is possible. Recipient diabetes and obesity appear to be independent negative prognostic indicators for survival after liver transplantation.³³

Fulminant Hepatic Failure

Acute hepatic failure, defined as the development of altered mental status, coagulopathy, and hepatic dysfunction within 8 weeks of the onset of an acute hepatic disease, is a rare but lethal disease.^{14,34} There are over 2,000 cases of acute hepatic failure per year in the United States. The mortality rate approaches 80% in patients who do not receive liver transplants. The causes of acute hepatic failure include viral hepatitis, toxins such as aflatoxins from the poisonous mushroom family *Amanita phalloides*, acute fatty liver of pregnancy, acute Budd-Chiari syndrome, and drug toxicities. Drug toxicities include both idiosyncratic reactions and drugs with predictable toxicity when taken in excess. Drugs that have been reported to induce idiosyncratic liver failure include isoniazid, halothane, valproate, disulfiram, and phenytoin, among many others. The over-the-counter analgesic acetaminophen causes dose-dependent hepatic failure and is now the single most common cause of acute hepatic failure in the United States.

The most generally accepted criteria for transplantation of patients with fulminant hepatic failure were described by the group at the King's College hospital in London, England (Table 36.5).³⁵ While the King's College criteria have been separately validated in other studies, more recent studies have begun to evaluate whether other scoring systems may have improved abilities to measure severity of illness. MELD has come under recent investigation in this regard and has been found to be additive to the King's College criteria in predicting outcome following fulminant hepatic failure.^{36,37} The current United Network for Organ Sharing (UNOS) listing criteria for patients with fulminant hepatic failure is in Table 36.2. The outcomes following transplantation have shown overall higher perioperative mortality, compared to other diseases, with overall similar long-term survival (Fig. 36.3).³

Biliary Atresia

Biliary atresia is a congenital disorder of infants that is characterized by biliary obstruction resulting from obliteration or discontinuity of the extrahepatic biliary system resulting in progressive hyperbilirubinemia, cirrhosis, and hepatic failure. The etiology is unknown yet is the most common indication for hepatic transplantation in pediatric patients. Standard treatment includes creation of a portoenterostomy (Kasai procedure), if this can be done before 3 months of age. After this point, success rates diminish markedly. Response to the portoenterostomy

TABLE 36.5

procedure is highly variable. Patients may develop cirrhosis within the first 6 months of life or live into their twenties before developing synthetic dysfunction and portal hypertension. Approximately 75% of children will require transplantation by 6 years of age.

It is critical that these patients are managed by an experienced pediatric gastroenterologist so that the correct window for effective transplantation can be identified and so they receive appropriate attention to their specialized nutritional needs. Specifically, deficiencies of fat-soluble vitamins that depend on bile for absorption are common and treatable. Transplantation is appropriate when children manifest growth and nutritional failure, when ascites develops, and when portal hypertension progresses to the point of variceal hemorrhage. Recurrent cholangitis is also thought to be an indication for liver transplantation. Transplantation for this population overall has had excellent results, with greater than 85% 10-year survival being achieved in the United States.³⁸ Factors that have been associated with improved survival include living donor transplants and older recipient age. Patients with significant growth failure generally have poorer outcomes.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC), thought to be autoimmune in nature, is characterized by gradually increasing serum bilirubin levels, progressive fatigue, and cirrhosis. Early stages of the disease are usually asymptomatic, and disease progression may evolve over 20 years. Treatment with ursodeoxycholic acid appears to slow the progression of the disease, but immunosuppression does not. It was once thought that primary biliary cirrhosis does not recur; however, histologic analysis has shown that the incidence of recurrence is approximately 15% within 5 years of transplantation.³⁹ Eventual progression to graft failure requiring retransplantation is possible, though rare.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an autoimmune disease that is characterized by gradually progressive inflammation of the biliary tree, eventually resulting in cirrhosis. PSC is associated with ulcerative colitis, but removal of the colon does not affect progression of the disease. In most cases, colectomy for associated inflammatory bowel disease is done after successful

transplantation because the failing liver makes the patient a poor candidate for a large abdominal procedure. PSC is also associated with the development of cholangiocarcinoma. Patients who experience a course that becomes rapidly progressive should be examined by endoscopic retrograde cholangiopancreatography (ERCP) with brushings to evaluate for cholangiocarcinoma. In addition to the usual considerations about the timing of transplantation, it is important to note that these patients are susceptible to bacterial cholangitis, which can cause systemic sepsis and rapid hepatic decompensation. Episodes of cholangitis that do not respond to suppressive antibiotic therapy should prompt early consideration for transplantation. Overall, patients with PBC or PSC experience the best outcomes with transplantation when compared to adults with other diseases; however, disease recurrence remains higher in PSC patients than in PBC patients.^{3,40}

Inherited Metabolic Disorders

Numerous inherited metabolic disorders are treatable by liver transplantation (Table 36.3). Some enzymatic deficiencies in this group result in destruction of the liver, so transplantation may resolve the liver failure as well as supply the missing enzyme. Disorders in this category include Wilson disease, α_1 -antitrypsin deficiency, tyrosinemia, and type I glycogen storage disease. In other cases, the liver is not affected by the disease, either structurally or functionally. In these circumstances transplantation is undertaken solely as enzyme replacement therapy. Diseases that have been cured by hepatic transplantation in this category include hemophilia A or B, homozygous familial hypercholesterolemia, Niemann-Pick disease, oxalosis, familial amyloid polyneuropathy, and numerous enzymatic deficiencies of urea cycle metabolism.⁴¹ Transplantation depends on determining that transplantation will cure the disease, or at least halt its progression, and that the consequences of the disease without transplantation are devastating, making transplantation appropriate.

Budd-Chiari Syndrome

Budd-Chiari syndrome is characterized by obliteration of the hepatic veins. It may be due to congenital webs of the hepatic veins or suprahepatic cava or may be caused by spontaneous thrombosis of the hepatic veins. The latter condition is associated with polycythemia vera and other hypercoagulable states. Diagnosis is made by inferior vena cavagram or magnetic resonance venography. The classic presentation is a triad of right upper quadrant pain, hepatomegaly, and ascites. Patients may present with fulminant hepatic failure during acute Budd-Chiari and have symptoms of encephalopathy and coagulopathy, or they may present in a more indolent fashion with ascites as the predominant feature. The natural history of the indolent form of Budd-Chiari syndrome is the eventual development of cirrhosis.

Patients who present with intact hepatic function should undergo an assessment to determine whether the liver has evidence of cirrhosis. A transjugular intrahepatic portosystemic shunt (TIPS) is the preferred therapy for patients who do not have evidence of synthetic failure and have not yet developed cirrhosis. Transplantation is reserved for cases where portal decompressive shunting is not possible or for patients who have advanced cirrhosis. Long-term anticoagulation to prevent recurrent hepatic vein thrombosis in the liver graft is routinely recommended.

Other Considerations

HPS and PPHTN are two other manifestations of cirrhosis whereby transplantation is justified. Similar to HCC, these two diseases can occur in cirrhosis despite overall preserved hepatic function and appear to involve dysregulation of vasoactive

mediators such as nitric oxide. Therefore, MELD exception scores are often sought when either HPS or PPHTN are present.¹² HPS is diagnosed on the basis of unexplained hypoxia in the presence of cirrhosis along with a positive “bubble” study for pulmonary shunt on echocardiography. PPHTN is diagnosed on the basis of pulmonary hypertension in the setting of cirrhosis without any other explainable etiology such as underlying pulmonary pathology. Recipient selection and management is critical to achieve reasonable success with liver transplantation. Patients with HPS experience the best outcomes if the preoperative partial pressure of arterial oxygen (PaO_2) is greater than 50 mm Hg.⁴² Patients with PPHTN likewise must have mean pulmonary artery pressures less than 35 mm Hg with or without medical therapy to experience a reasonable chance of recovery following liver transplantation.^{43,44}

In addition to isolated liver disease, liver transplantation is occasionally considered along with other solid organ transplantation. The two most notable examples are combined kidney and liver transplantation as well as combined liver and intestine transplantation.⁴ Intestine transplantation is usually performed in cases where intestinal failure is present along with progressive cholestatic liver failure secondary to hyperalimentation.⁴⁵ Since hepatorenal syndrome frequently occurs with advanced cirrhosis and also frequently resolves with successful liver transplantation, the indications for combined liver and kidney transplantation are more controversial.⁴⁶ It is widely accepted that preexisting end-stage renal disease along with significant cirrhosis or the existence of hepatorenal syndrome requiring 8 or more weeks of renal replacement therapy warrants consideration of combined liver and kidney transplantation. Ongoing investigations are required to define patients with hepatorenal syndrome who are less likely to recover renal function following liver transplantation.

LIVER TRANSPLANTATION: SURGICAL PROCEDURE

Anesthetic Management

An anesthesiologist with experience in liver transplantation is invaluable to the transplant team, and liver transplant anesthesiology is rapidly becoming a subspecialty. Proper anesthetic management and effective communication between the surgery and anesthesiology teams is necessary to optimize patient care during the surgical procedure. While an extensive outpatient preoperative evaluation is usually performed, including cardiac risk stratification, many liver candidates report from home when a liver becomes available. If adequate time for fasting has not occurred, consideration of rapid sequence induction should be given to prevent aspiration. After induction and intubation, general anesthesia is maintained with a combination of inhalational agents and the administration of paralytic agents and analgesics. For adult patients, cardiac monitoring is often performed either by pulmonary artery catheterization or intraoperative transesophageal echocardiography. An arterial catheter is placed for blood pressure monitoring. Adequate vascular access, often including central venous catheters, is required for the administration of blood products and the potential for rapid resuscitation in the case of massive blood loss. A device for rapid infusion and the ability to warm blood products or intravenous fluids is advisable. Low central venous pressures maintained during the hepatectomy phase of the procedure may help avoid excess bleeding.

Intraoperative Management of Coagulopathy

Liver transplantation has the potential for massive blood loss for several reasons. Liver transplant candidates with cirrhosis often have synthetic deficiencies in circulating coagulation factors as well as severe portal hypertension associated with

thrombocytopenia and extensive venous collaterals. Intraoperative coagulopathy may be worsened during the anhepatic phase of the procedure. Finally, liver transplantation involves extensive dissection of major vascular structures including the inferior vena cava, portal vein, and hepatic artery, all with an inherent risk for torrential bleeding.

Intraoperatively, coagulation is monitored by frequent determination of standard parameters including prothrombin time, partial thromboplastin time, platelet count, and fibrinogen. Abnormalities of these laboratory values associated with intraoperative bleeding are often corrected with fresh frozen plasma, platelets, or cryoprecipitate. Normal coagulation is also helped by maintaining normal pH, calcium levels, and normothermia. Intraoperative thromboelastography (TEG) can facilitate decision making by rapidly identifying which components of the coagulation cascade are deficient or by identifying the presence of a fibrinolytic state. However, the device for TEG can be fragile and overly sensitive, which may limit its practical use in the clinical setting. The decrease in excessive bleeding in the modern era of liver transplantation has led to many programs abandoning the routine use of TEG. While the administration of recombinant factor VII intraoperatively can rapidly and effectively stop non-surgical bleeding, its use has a theoretical risk of postoperative thrombotic complications including hepatic arterial thrombosis. In addition, no definitive data have been demonstrated to decrease the need for intraoperative blood transfusions.^{47,48} Therefore, its use is only recommended in emergent situations.

Following reperfusion of the donor liver, a fibrinolytic state may be encountered. This is related to the lack of production of fibrinolysis inhibitors during the anhepatic phase and the inability of the liver to metabolize profibrinolytic compounds. This state may be identified either by thromboelastography, recurrence of bleeding where hemostasis had been previously obtained (such as the wound edge), or extensive and refractory bleeding after revascularization. This state may be treated with the use of antithrombotic agents including ϵ -aminocaproic acid, tranexamic acid, or aprotinin. Because therapy with antithrombotic agents has been associated with intravascu-

lar thrombus formation, it should not be used routinely and should be discontinued when no longer needed.

Surgical Technique

Transplantation of the liver is among the most technically demanding surgical procedures. During induction and placement of the appropriate monitoring lines by the anesthesiology team, the donor liver is prepared on the back table for implantation (Fig. 36.4). Bench preparation includes resection of the donor diaphragm and adrenal gland off of the bare area of the liver and vena cava. Meticulous ligation of tributaries from the vena cava (adrenal vein, phrenic vein, and lumbar branches) is performed. The artery is dissected free from the Carrel patch of the aorta up to the gastroduodenal artery. Dissection near the right or left hepatic arteries is avoided to prevent unnecessary injury. The portal vein is circumferentially dissected free. The gallbladder may be removed at this stage or following reperfusion. Tissues surrounding the common bile duct are left intact to avoid injury of the blood supply.

Following this, the recipient's abdomen and bilateral groins are prepped and draped in a standard fashion. The most commonly used incision is a bilateral subcostal incision with a midline extension to the xiphoid process (Fig. 36.4B). After dividing the fascia, ascites, which can occasionally be present in a large volume, is evacuated. The ligamentum teres hepatis is carefully divided between clamps and ligated because a large recannulized umbilical vein is often present in patients with severe portal hypertension. After dividing the falciform ligament with cautery, a mechanical retractor is used to retract the bilateral costal margins anteriorly and superiorly for excellent exposure of the upper abdomen. The abdominal cavity and liver are then inspected for any abnormalities including unsuspected malignancy, particularly within the cirrhotic liver, which is a risk factor for hepatocellular carcinoma. Following this, liver transplantation occurs in three stages: (a) recipient hepatectomy, (b) anhepatic phase, and (c) postrevascularization.

FIGURE 36.4. A: The donor liver after excision and before transplantation. B: Bilateral subcostal incision with a subxiphoid extension.

Recipient Hepatectomy

During the recipient hepatectomy phase, the liver is mobilized from its ligamentous attachments and the porta hepatis is skeletonized. Attention is first directed to dissecting and skeletonizing the structures of the portal triad. The peritoneum overlying the portal triad is divided with electrocautery near the liver edge. The right and left hepatic arteries are dissected free, ligated, and divided, leaving adequate length to form a branch patch for the arterial anastomosis. The proper hepatic artery is also dissected free to the level of the gastroduodenal artery allowing enough length for clamping during the anastomosis. Because portal venous flow of blood to the liver may be hepatofugal (away from the liver), division of the artery may leave the patient functionally anhepatic. If a prolonged period of time is expected for mobilization of the liver, such as when extensive adhesions are present, the artery may be dissected free but left in continuity to allow whatever synthetic capacity the native liver has to continue. A replaced or accessory right hepatic artery, which arises as a branch off the superior mesenteric artery and travels in a posterior position to the common bile duct and lateral to the portal vein, can usually be palpated if present and can be ligated and divided. When the replaced right hepatic artery is relatively large and the proper hepatic artery is diminutive in size, the replaced right hepatic artery can be left long and used for arterial inflow for the donor liver. A replaced or accessory left hepatic artery arises from the left gastric artery if present and can be identified by inspection of the pars flaccida of the lesser omentum along the lesser curvature of the stomach (Fig. 36.5).

Conceptually, the common bile duct and common hepatic duct should be dissected free with as much length as possible and without injuring the blood supply to the bile duct. Leaving the recipient bile duct as long as possible allows the length of the donor bile duct, which may have a tenuous blood supply, to be shorter and still avoid tension at the time of anastomosis. This is accomplished by first ligating and dividing the cystic duct. The common bile duct and common hepatic duct are then circumferentially dissected free leaving the surrounding tissue to preserve the bile duct blood supply. The common hepatic duct is then ligated as close to the native liver as possible.

Once the bile duct and the hepatic artery are freed from surrounding tissues, the portal vein can be easily approached

from its anterior, medial, and lateral aspects. In general, the portal vein is freed circumferentially from the edge of the duodenum up to its bifurcation of the right and left portal veins. Small branches may arise near the pancreas and excessive bleeding may arise if these are inadvertently injured. Most patients with severe portal hypertension will not develop hypotension, small bowel edema, or ischemia if the portal vein is clamped and divided because of the presence of portal venous collaterals. However, patients without portal hypertension, such as those undergoing liver transplantation for fulminant hepatic failure or metabolic deficiency or those who have had a TIPS for a prolonged period of time, may develop extensive small bowel edema or hypotension when the portal vein is clamped. Small bowel edema can lead to limited exposure in the right upper quadrant, making implantation of the liver extremely difficult. In these situations, the portal vein should be left in continuity for as long as possible, particularly when the use of venovenous bypass is not intended. For those patients with portal vein thrombosis, portal venous flow can be restored in most cases. Often, the thrombus can be evacuated with the use of forceps or by placing a Yankauer suction tip within the lumen of the portal vein. If the thrombus is more mature, an eversion endovenectomy may be necessary.⁴⁹ If these maneuvers are unsuccessful, the junction of the splenic vein and superior mesenteric vein may be patent. Dissection of the portal vein behind the pancreas to this junction can then be performed to allow for future anastomosis. Dissection to the confluence of the splenic and superior mesenteric veins is sometimes necessary in pediatric recipients because of the small caliber of the portal vein within the porta hepatis. In rare cases, all of these maneuvers may be unsuccessful and a venous bypass graft from the superior mesenteric vein may be necessary. If the superior mesenteric vein is also occluded, the inferior vena cava can be used for portal inflow, a procedure termed cavoportal hemitransposition.⁵⁰ This procedure is associated with acceptable outcome despite the fact that portal hypertension may not be alleviated. A fourth option is arterIALIZATION of the portal vein, using a conduit created by anastomosing donor iliac vessels to the recipient aorta and connecting this to the donor portal vein.⁵¹

The ligamentous attachments of the liver, including the left and right triangular and coronary ligaments, are then divided using electrocautery. The bare area of the liver is dissected along a plane just superficial to the capsule of the liver. Care

FIGURE 36.5. A replaced left hepatic artery usually arises as a branch of the left gastric artery, traversing the pars flaccida of the lesser omentum from left to right toward the left lobe of the liver.

must be taken to avoid injury to the phrenic or hepatic veins when freeing the suprahepatic inferior vena cava where it traverses the diaphragm. The hepatocaval ligament along the right lateral aspect of the vena cava can be divided using a combination of cautery and ligation as a phrenic venous branch is often present within this ligament. The liver is then dissected off of the anterior aspect of the inferior vena cava. Small venous branches from the inferior vena cava to the caudate lobe are ligated and divided. Larger branches, such as an accessory right hepatic vein, are clamped, divided, and oversewn. Division of the portal vein facilitates exposure for this dissection but is not required. The liver may be gradually retracted and dissected from either the right or left aspects until the right, middle, and left hepatic veins are reached. If a bicaval venous anastomosis technique will be used, the vena cava can be circumferentially mobilized near the diaphragm above the hepatic veins as well as in an infrahepatic position. However, if a piggyback or cavocavostomy (side-to-side caval anastomosis) technique is intended, the dissection of the posterior aspect of the vena cava should be avoided to prevent encountering unnecessary bleeding from collateral or lumbar venous branches in this area.

Anhepatic Phase and Implantation of the Donor Liver

At this point, the liver has been completely mobilized except for its attachments of the hepatic veins to the inferior vena cava and, in some cases, the portal vein. The decision should now be made whether to use venovenous bypass. Most patients will tolerate clamping of both the portal vein and the inferior vena cava without difficulty.⁵² At this point, communication with the anesthesiologist is essential and the vena cava should be test

clamped before division to make sure that adequate cardiac filling and blood pressure can be maintained. If the patient becomes hypotensive during test clamping, the clamp should be removed and additional volume or pressor support can be administered. Occasionally, patients will require venovenous bypass, but its use is no longer routine at most centers.

If necessary, venovenous bypass can be accomplished from both the portal vein and inferior vena cava simultaneously, or a single cannula in either the portal vein or the inferior vena cava may be used (Fig. 36.6). There are several accepted methods of placing cannulas for venovenal bypass. Cannulas may be placed percutaneously in the internal jugular vein and femoral vein prior to beginning the procedure. These cannulas are advanced into the superior and inferior vena cava, respectively. Alternatively, one or both of the bypass cannulas may be placed by cutdown on the axillary and/or greater saphenous vein. Inferior vena caval and mesenteric blood is delivered to the superior vena cava by a centrifugal pump. The cannulas, tubing, and centrifugal pump head are heparin bonded to reduce the chance of thrombus formation and subsequent embolism without the use of anticoagulation. Flow rates of 1 to 2 L/min are usual.

Once venovenous bypass has been established or the decision to forego bypass has been made, the recipient hepatectomy is completed. If still intact, the portal vein is divided as high in the hilum as possible. Three methods are commonly used for orthotopic liver transplantation: (a) the bicaval technique, (b) the piggyback technique, and (c) cavocavostomy (side-to-side caval technique).

1. For the bicaval technique, the recipient liver is excised en bloc with the retrohepatic inferior vena cava after caval clamps have been placed in a suprahepatic and infrahepatic position. The hepatic veins are divided within the substance

FIGURE 36.6. Setup for venovenous bypass during hepatic transplantation. Cannulas are placed into the portal vein to decompress the splanchnic bed and inferior vena cava (through the greater saphenous vein) to decompress the lower extremities and kidneys during the anhepatic phase of the transplantation. A centrifugal pump is used to deliver bypassed blood to the central circulation by means of a cannula passed into the axillary vein.

FIGURE 36.7. **A:** The diseased recipient liver is removed by incising the liver below the level of the hepatic veins. **B:** The hepatic veins are then opened to form a large suprahepatic cuff for anastomosis. The suprahepatic vena caval anastomosis: posterior suture line (**C**) and anterior suture line (**D**).

of the liver to allow the creation of a large suprahepatic cuff compromising the left, middle, and right hepatic veins (Fig. 36.7). This technique has the disadvantages of (a) totally obstructing inferior vena cava flow, resulting in renal ischemia and decreased cardiac filling with associated hypotension, possibly leading to the requirement of venovenous bypass; (b) requiring two vena caval anastomoses, prolonging the warm ischemic time; and (c) requiring dissection posterior to the vena cava, possibly leading to bleeding. However, complete dissection of the caudate lobe off of the vena cava is not necessary, making the recipient hepatectomy phase somewhat easier and faster.

- For the piggyback technique, a clamp is placed transversely, partially occluding the vena cava at the level of the hepatic veins. The vena cava is left in continuity and the hepatic veins are divided within the substance of the liver, allowing the creation of a common patch of the right, middle, and left hepatic veins for a wide anastomosis. While the intention is to only partially occlude the vena cava, allowing venous return to the heart, often a clamp placed for the piggyback technique either occludes or nearly occludes the inferior vena cava. This technique does have the advantage of only requiring a single vena caval anastomosis, helping to limit warm ischemic time. However, torsion may occur if

FIGURE 36.8. Cavocavostomy. **A:** The recipient right and junction of the middle and left hepatic veins are stapled and the inferior vena cava is left in continuity. **B:** The supra- and infrahepatic vena cavae are stapled and a venotomy is made longitudinally on the posterior aspect of the donor liver. **C:** A side-to-side caval anastomosis is performed with a running suture.

the right upper quadrant is relatively large, such as when a large volume of ascites is present, and the donor right hepatic lobe is relatively small. This may lead to right hepatic vein or inferior vena caval stenosis.

3. For the cavocavostomy technique, clamps can be placed on the right hepatic vein as well as the junction of the left and middle hepatic veins. The liver is excised and these venous branches are oversewn and the clamps are removed. Alternatively, the hepatic veins can be divided using an Endo GIA stapler (Fig. 36.8). Advantages of the cavocavostomy anastomosis include (a) minimalization of the time that the vena cava is clamped; (b) the vena caval clamp is placed longitudinally, only occluding the anterior third of the vena cava, leading to minimal or no changes in the recipient's hemodynamics; (c) a cavoplasty is performed, limiting the likelihood of caval stenosis; (d) a long anastomosis is performed, often over 6 cm in length, minimizing the risk for hepatic vein outflow complications; and (e) exposure during suturing of the anastomosis is considerably improved compared to the piggyback or bicaval technique.

After removal of the recipient liver, the right upper quadrant is carefully inspected and hemostasis is obtained. Complete hemostasis in the bare area is essential at this time because this region is easily visualized when the liver is absent but may be relatively inaccessible once the donor liver is implanted, especially if the donor liver is relatively large or the recipient is obese. Argon beam coagulation can also be used to aid in hemostasis at this point.

The donor liver is then brought onto the operative field. The vascular anastomoses are performed using a running monofilament polypropylene suture. If a bicaval technique is planned, two caval anastomoses are required. The suprahepatic vena

caval anastomosis is first performed by suturing the posterior walls from within the lumen using an imbricating technique (Fig. 36.7). The anterior wall is then completed. The infrahepatic anastomosis is then completed in a similar fashion. Redundancy in the donor vena cava is avoided to prevent the potential for kinking. The completion of the anastomosis may be left until the time of hepatic revascularization to provide a vent for air and acidotic or hyperkalemic blood and for residual preservation solution. Venting of blood prior to reperfusion is most important if preservative solutions containing a high concentration of potassium, such as University of Wisconsin solution, are used. Venting of blood is less critical if preservative solutions that do not contain high concentrations of potassium are used, but care must still be taken to avoid the rapid bolus of air or cold blood to the heart. For the piggyback technique, the donor infrahepatic vena cava is either oversewn or stapled. The donor infrahepatic vena cava is then sewn in an end-to-side fashion to the recipient hepatic vein cuff (Fig. 36.9). As described earlier, an imbricating suture technique is often helpful to prevent gaps in the anastomosis and to compensate for size discrepancies. Venting at the time of reperfusion can either be performed through the suprahepatic anastomosis or at the donor infrahepatic vena cava. For the side-to-side caval technique, a clamp is placed longitudinally on the anterior third of the recipient vena cava. A longitudinal venotomy is made on the anterior surface of the recipient vena cava. The donor suprahepatic and infrahepatic vena cavae are either oversewn or stapled closed. A longitudinal posterior venotomy is then made matching the length of the recipient venotomy. The liver is then placed in the right upper quadrant and the left lateral segment is elevated. The two vena cavae are then sutured in a side-to-side fashion with the lateral wall sutured from within the lumen and the medial wall sutured from outside the lumen

FIGURE 36.9. A: Recipient liver is dissected off the native inferior vena cava by dividing veins draining directly into the inferior vena cava up to the level of the hepatic veins. B: Clamp is placed on recipient hepatic veins in preparation of excision of the recipient's native liver and performance of a piggyback anastomosis.

(Fig. 36.8). Venting can be performed from either the suprahepatic donor vena cava or the medial wall of the anastomosis. During the caval anastomosis, the donor liver may be perfused with cold fluid via a cannula placed within the donor portal vein to wash out the preservation solution and to help maintain the cold temperature of the liver. This step is not required but may be considered if the liver was preserved with a solution containing a high concentration of potassium or if a prolonged warm ischemic time is anticipated.

Once the caval anastomosis or anastomoses are completed, either the portal anastomosis, arterial anastomosis, or both can be performed prior to reperfusion. In theory, reperfusion with arterial blood would limit the extent of warm ischemia to the biliary tree, which, unlike the remainder of the liver, receives its blood supply exclusively from the arterial blood and not along with portal venous blood. However, neither sequence has been clearly shown to be an advantage over the other, so the choice is made based on the surgeon's preference and the patient's anatomy. Most commonly, the portal venous anastomosis is completed and the liver is reperused. If portal bypass has been used, the portal limb of the venovenous bypass circuit is removed. The portal anastomosis is usually performed in an end-to-end fashion using a running technique. To avoid narrowing, an air knot is used when the suture is tied.

At the time of revascularization, flow is restored to the liver through the portal vein and/or the hepatic artery. The first several hundred milliliters of blood may be vented through the infrahepatic vena cava and the knot can be tied completing the caval anastomosis. Alternatively, the caval clamp can be "flushed" and the anastomosis inspected for bleeding and repaired if present. If blood is not vented through the infrahepatic vena cava, portal blood should be restored gradually to minimize cardiac irritability, bradycardia, and hypotension, all of which routinely result from cold blood circulating through the donor liver and going directly into the right atrium. Close coordination between the surgeon and anesthesiologist is necessary during this phase as hypotension and bradycardia are routinely encountered and cardiac arrest may rarely occur. If venovenous bypass has been used during the anhepatic phase, it can now be discontinued.

Once hemostasis is obtained and the patient has stabilized, attention can now be turned toward the arterial anastomosis if it has not already been performed. Conceptually, the arterial anastomosis can be performed in one of two ways. The anas-

tomosis can be performed with the artery being long, which allows the artery to lie with a smooth and gentle curve or loop (Fig. 36.10). For this technique, all branches on the donor artery are ligated and the donor aortic Carrel patch, celiac artery, or branch patch of the celiac and splenic artery is anastomosed in an end-to-end fashion to a branch patch of the recipient right and left hepatic arteries (Fig. 36.11). Alternatively, the artery can be cut to just the right length and sewn in an end-to-end fashion. This is often performed by forming branch patches between the donor and recipient proper hepatic and gastroduodenal arteries and performing the anastomosis in an end-to-end fashion. However, when the retractor is released, the liver may shift position and kinking of the artery may occur. Therefore, judging the proper length of the arteries may be difficult and this technique may be more technically demanding than the method that leaves the artery way too long. If the artery is somewhat long but not long enough to allow a gentle or smooth curve or loop, kinking and obstruction to blood flow may occur. For both techniques, the anastomosis can be performed using a fine, nonabsorbable, monofilament, running suture. If the recipient arterial inflow is inadequate, an aortic conduit may be constructed. This is often performed using a

FIGURE 36.10. Hepatic artery anastomosis where the artery is left long to allow for a gentle loop or curve to form.

FIGURE 36.11. A: The donor hepatic artery is procured with a Carrel patch of aorta. B: The recipient hepatic artery bifurcation is used to fashion a branch patch for a larger anastomosis. C: The anastomosis is carried out using continuous monofilament suture material. D: The completed anastomosis.

graft consisting of the donor common and external (or internal) iliac artery. A partially occluding aortic clamp can either be placed in a supraceliac or infrarenal position and the common iliac artery is sutured in an end-to-side fashion to the recipient aorta. The donor Carrel patch can then be sutured in an end-to-end fashion to the external iliac artery of the conduit.

Postrevascularization Phase

Following revascularization, the liver should assume a normal color and consistency within several minutes. If the liver remains pale or is overly soft, problems with portal inflow should be considered. Alternatively, if the liver becomes ede-

matous and overly firm, outflow obstruction should be excluded. Bile production should be seen while in the operating room and is among the first evidence for liver function. In contrast, watery or milky fluid from the bile duct raises concern for primary nonfunction. Inspection for surgical bleeding should be performed and entails examination of the vascular anastomoses as well as a search for branches of the major vessels that may not have been ligated. If bleeding continues after all surgical bleeding has been resolved, attention should be directed toward correction of coagulopathy as described earlier.

While biliary reconstruction does not carry the same risk for intraoperative disaster when compared to the recipient hepatectomy and reperfusion, it is associated with considerable postoperative morbidity and mortality and requires the same diligence and attention as other steps of the operation. Because of the relatively high complication rate associated with biliary reconstruction, it has been referred to as the “Achilles heel” of liver transplantation. There are several options for biliary reconstruction. In the past, the Calne conduit, or the use of the donor gallbladder, was used but has been abandoned due to the high rate of biliary complications associated with it. The simplest and most common technique is currently an end-to-end choledochocholedochostomy from the donor to the recipient bile duct (Fig. 36.12). If a size discrepancy exists, the narrower duct can be spatulated. Running or interrupted sutures can be used. Absorbable monofilament suture is most commonly used to avoid a nidus for future stone formation within the bile duct. While T-tubes were commonly used in the past to stent the anastomosis, evidence now suggests that more leaks or strictures develop as a result of the T-tube than are prevented. Internal biliary stents may be used and may help prevent leaks or strictures.⁵³ Alternative biliary reconstruction methods may be necessary for those with a bile duct of inadequate quality or size or in those whose primary disease is biliary pathology such as primary sclerosing cholangitis or biliary atresia. The most common option employed in these situations includes a standard Roux-en-Y choledochojejunostomy. If a choledochojejunostomy had been performed in the past, the limb of small bowel used may often be salvaged and used for biliary drainage of the new liver. Placement of drains is optional but may help identify and treat biliary leaks. Abdominal wall and skin closure is then performed in the standard fashion.

Technique for Reduced-size and Split Liver Transplantation

In the 1980s, the waiting list mortality for small, pediatric liver candidates was relatively high because the number of suitably sized small liver donors was inadequate. As a result, techniques to reduce the size of an adult liver, based on Couinaud’s segmental anatomy (Fig. 36.13), were developed so that the left lobe, left lateral segment, or even a single segment could be used for a recipient more than 10 times smaller by weight than the donor.^{54,55} During the early experience, the donor hepatectomy was performed in a standard fashion and the liver was brought back to the recipient hospital. The needed segments of the liver were cut down on the back table with the organ on ice, the vessels were left intact to the future transplant graft, and the remainder of the liver was discarded. Techniques have now developed so that both sides of the liver can be transplanted into two recipients, either a child and an adult or two adults.^{56,57} In addition, the liver may be split in situ at the donor hospital, allowing coagulation of the cut edge of the liver so that bleeding is minimized following reperfusion. Perfusion to both sides of the liver can be inspected prior to flushing, ensuring that blood flow to all segments of each future graft has been preserved. Because of technical and practical issues, both the cut-down technique and in situ splitting of the liver are still employed. Split liver transplantation has been

FIGURE 36.12. A: In most cases, a choledochocholedochostomy is performed, possibly over an internal stent. B: Patients with a diseased or unsuitable common bile duct require biliary reconstruction with a Roux-en-Y choledochoenterostomy.

associated with a decreased survival rate and the potential for increased risk of complications, including primary nonfunction, hepatic artery thrombosis, and biliary complications. Because of this, while widespread adoption of allocation policies to encourage greater utilization of split liver grafts in the adult population has been suggested, split liver transplantation only accounts for a small proportion of transplants performed. In addition, only grafts from “ideal donors” are thought to be suitable for this form of transplantation. Criteria supported by UNOS for splitting currently include that the donor be less than 40 years of age, be on a single pressor or no pressors, have transaminases no greater than three times normal, and have a body mass index of 28 or less.

Living Donor Liver Transplantation

Experience with deceased donor split liver transplantation as well as the success with living donor kidney transplantation led to the adoption of the techniques for split liver transplantation to living donor liver transplantation. The first living donor liver transplantation allowed an adult volunteer to donate the left lateral segment of the liver to a child. Based on the success of living donation in the pediatric population as well as the increased waiting list mortality rate for adults, these techniques have also been applied to adult recipients receiving either the right or left lobe from an adult volunteer.⁵⁸

FIGURE 36.13. Segmental anatomy of the liver as based on Couinaud's nomenclature.

FIGURE 36.14. Living donor right hepatic lobe allograft demonstrating the right hepatic vein (RHV), right portal vein (RPV), right hepatic artery (RHA), and two right hepatic ducts.

Living donor liver transplantation was progressively developing in the United States until a well-publicized donor mortality occurred.⁵⁹ Living donor liver transplantation now accounts for approximately 5% of all liver transplants performed in the United States. In Japan and other areas of the Far East, where deceased donor transplantation has developed more slowly because of cultural difficulties with the concept of brain death, living donor transplant is the rule rather than the exception.

In many respects, transplantation of a graft from a living donor is similar to transplantation of a whole liver from a deceased donor. However, a bicaval technique is not possible given that the donor vena cava is not available for replacement of the recipient's retrohepatic inferior vena cava (Fig. 36.14). Therefore, the recipient vena cava must be left intact. A direct hepatic vein to vena caval anastomosis is used (Figs. 36.15 and 36.16). Establishing adequate outflow of hepatic venous blood

FIGURE 36.15. Left lateral segment (segments II and III) living donor transplantation. **A:** Donor operation. **B:** Recipient operation completed.

FIGURE 36.16. Right lobe (segments V to VIII) living donor transplantation. **A:** Donor operation. **B:** Recipient operation completed.

is necessary to prevent edema of inadequately drained segments of the liver possibly leading to small-for-size syndrome. Therefore, any accessory veins greater than 5 mm in diameter should be reconstructed either by direct anastomosis to the vena cava or by using an interposition graft. In addition, the lengths of the portal vein, hepatic artery, and bile duct on the donor graft are considerably shorter than those available from a deceased donor. Therefore, during the recipient hepatectomy, considerable care should be given to preserving the length of the recipient bile duct as well as the right and/or left hepatic artery and portal vein that are intended for future anastomosis.

Auxiliary Liver Transplantation

Under select circumstances, there is a good rationale for placing the donor allograft in heterotopic rather than orthotopic position, leaving the native liver in place. This procedure is known as auxiliary liver transplantation. Auxiliary liver transplantation has occasionally been used for cases in which liver transplantation is indicated for enzymatic deficiency but the native liver is otherwise normal in all other respects. It has also been used in cases of fulminant hepatic failure where the liver candidate is expected to die in the near future without transplant but if adequate time was allowed, the native liver may recover and return to normal. In this situation, immunosuppression can slowly be weaned, the transplanted liver will atrophy, and the recipient can be taken off of all immunosuppression. Figure 36.17 demonstrates one technique used. Another option, auxiliary partial orthotopic liver transplantation (APOLT), has been developed. For this technique, part of the native liver is resected, often the right trisegment, leaving only the left lateral segment intact. The donor liver is then transplanted in an orthotopic position. If the native left lateral segment recovers, immunosuppression can be weaned, leading to hypertrophy of the left lateral segment and involution of the allograft.

COMPLICATIONS

3 The degree of preoperative debilitation and the complexity of the operative procedure make complications following liver transplantation very common. Prompt recognition and treatment are essential. However, the usual signs or symptoms that would be expected in the general population are often absent or present to a lesser degree, and therefore, a high level of sus-

picion must be maintained. Early warnings, such as fever, leukocytosis, or pain, may be suppressed as a result of immunosuppression. In addition, the burden of immunosuppression predisposes to additional problems not usually encountered in other areas of surgery. In the following sections, some of the major surgical complications that occur after liver transplantation are described.

Primary Nonfunction

4 About 2% to 10% of transplanted livers function so poorly in the immediate postoperative period that death is likely in the absence of retransplantation. This circumstance is referred to as primary nonfunction. Most cases of primary nonfunction likely occur as a result of ischemic injury, occurring either in the donor or the recipient,⁶⁰ or from poor preservation. Donor factors known to predispose to primary nonfunction include allograft steatosis, advanced donor age, and prolonged cold ischemic time. In addition, donor race and the need for portal vein reconstruction have also been demonstrated to be risk factors for primary nonfunction.⁶¹

Early evidence for primary nonfunction includes poor bile production of the liver intraoperatively, refractory acidosis, progressive coagulopathy, and hepatic encephalopathy. In a short period of time, these early signs are often followed by acute renal insufficiency and eventually cardiopulmonary collapse. Serial factor V levels may be helpful to determine if a liver allograft is functioning in a patient who has received a massive transfusion of fresh frozen plasma. In this setting, the INR may reflect transfused coagulation factors rather than factors emphasized by the liver graft. Fresh frozen plasma contains relatively little factor V because this factor is relatively unstable in cold storage. Therefore, a steady increase in the factor V level suggests production by the liver rather than transfusion with fresh frozen plasma.

Liver transplant recipients in the United States with primary nonfunction, currently defined as those who were transplanted within 7 days and are anhepatic or those who have developed an aspartate transaminase above 3,000 along with an INR above 2.5 and/or acidosis, can be relisted as a status 1A. Patients listed as a status 1A receive regional priority over less ill patients and frequently wait only a period of a few days for an appropriate donor to become available. Despite this preferential listing for retransplantation, primary nonfunction is associated with a mortality rate of more than 50%.⁶¹

FIGURE 36.17. Heterotopic auxiliary liver transplantation using a reduced-size allograft.

Postoperative Hemorrhage

Postoperative hemorrhage requiring laparotomy occurs in approximately 5% to 15% of liver transplant recipients. Postoperative bleeding should be suspected in any liver recipient during the immediate posttransplant period who develops tachycardia, volume-dependent hypotension, oliguria, and abdominal distention. Because many liver transplant recipients may have had a large volume of ascites preoperatively (sometimes more than 10 to 20 L), a considerable amount of bleeding may occur before developing an abdominal compartment syndrome. In general, attempts to correct coagulopathy should be made and reexploration should occur in patients with refractory hypotension, abdominal compartment syndrome, or ongoing need for blood transfusion. At exploration, a specific bleeding point often cannot be identified, suggesting that bleeding may be related more to coagulopathy than failure of surgical hemostasis. Therefore, waiting until coagulopathy is corrected before reexploration may be wise, assuming that the recipient is otherwise reasonably stable.

Hepatic Artery Thrombosis

The incidence of hepatic artery thrombosis ranges from 1% to 2% up to 10% in some populations. The incidence of hepatic

artery thrombosis is higher in pediatric recipients and recipients of living donors or split livers. Other risk factors include receiving a liver from a donor who is significantly smaller than the recipient, the need for reconstructive arterioplasty in the presence of nonstandard donor anatomy, acute rejection within the first week posttransplant, placement of cytomegalovirus (CMV)-positive organs into CMV-negative recipients, and a recipient history of smoking.⁶² The association between rejection and hepatic artery thrombosis may be the result of a decrease in hepatic arterial flow that occurs when the liver is swollen and edematous or of release of procoagulants into the microcirculation in association with the inflammatory injury of graft rejection.

Hepatic artery thrombosis can occur in the early period, arbitrarily defined as within 30 days, or late posttransplant period. Early hepatic artery thrombosis is usually identified within the first 10 days posttransplant. The diagnosis is suspected in the setting of unexpectedly high liver enzymes, an elevation in liver enzymes rather than a gradual decline, or poor synthetic function during the first week to 10 days posttransplant. Other signs of biliary ischemia from hepatic arterial thrombosis include the development of biliary leaks, strictures, or intrahepatic abscesses. Doppler ultrasonography is usually used to confirm flow within the extrahepatic and intrahepatic arteries. If inappropriate waveforms or no flow is identified, the diagnosis can be confirmed by angiography or reexploration. At exploration, flow can be restored within the

hepatic artery approximately 80% of the time if the diagnosis is made early. However, despite restoring arterial flow, many of these recipients will still develop biliary complications.

Hepatic artery thrombosis that occurs months to years following liver transplantation does not always lead to graft failure. Although some patients develop biliary strictures and/or hepatic abscesses, approximately a third of patients do well without intervention.⁶³

The rate of arterial blood flow in the reconstructed hepatic artery is an important determinant of long-term patency. It is believed that children are predisposed to hepatic artery thrombosis because they have smaller vessels and lower mean arterial blood pressure than adults. Pediatric patients with an arterial diameter of less than 3 mm have the highest incidence of hepatic artery thrombosis. However, the experience with pediatric living donor transplantation, where very small arteries are routinely encountered, has indicated that with microsurgical technique it is possible to achieve a low hepatic artery thrombosis rate.⁶⁴

A postoperative hypercoagulable state associated with hepatic transplantation may predispose to hepatic artery thrombosis. Relatively poor hepatic production of natural regulatory anticoagulants, such as proteins C and S and antithrombin III, immediately after transplantation promotes coagulation because production of procoagulant factors, such as factor V and VII, occurs more rapidly after revascularization.⁶⁵ This observation has prompted some centers to administer fresh frozen plasma as a source of antithrombin III and proteins C and S in the postoperative period. Most centers recommend prophylactic aspirin to prevent hepatic artery thrombosis in children, although no objective data demonstrate the value of this practice.

Portal Vein Thrombosis

Postoperative portal vein thrombosis is much less common than hepatic artery thrombosis, occurring in 1% to 3% of cases. A higher incidence of portal vein problems is seen in patients who have had previous portal vein operations or prior thrombosis of the portal system. Factors that decrease antegrade portal flow also predispose to portal vein thrombosis. Patients with chronic portal hypertension often spontaneously develop large retroperitoneal collaterals from the portal venous system to the renal vein and inferior vena cava. A previous surgically created splenorenal shunt should be disconnected at the time of transplantation because it usually is associated with reduced flow through the portal vein. This can be accomplished easily during a liver transplant by dissecting down the vena cava and ligating the left renal vein at its origin. This maneuver does not compromise the function of the left kidney. This maneuver can also be useful to improve portal flow if preoperative imaging discloses large spontaneous portal-systemic shunts to the left renal vein.

Portal vein thrombosis should be suspected when the recipient develops symptoms of portal hypertension or ascites that is unusually difficult to control. Doppler ultrasound examination is usually the first diagnostic tool, but magnetic resonance imaging is also an option, as are standard mesenteric arteriography with portal phase views and direct percutaneous transhepatic portography. Transhepatic portography is particularly useful if a stenosis, rather than thrombosis, is identified because it is possible to both measure the pressure gradient across a stenotic area and treat a stenotic area with angioplasty and/or stent placement.

When portal vein thrombosis is identified in the immediate postoperative period, reexploration and attempted thrombectomy are usually indicated. Thrombectomy is more likely to be successful if a technical flaw in the anastomosis is present and can be corrected. When performing thrombectomy, it is advisable to avoid using balloon embolectomy catheters to remove clot from the mesenteric venous system, because these veins

are very fragile and rupture of mesenteric veins deep in the mesentery can be catastrophic.

Hepatic Vein or Inferior Vena Cava Stenosis

Thrombosis of the inferior vena cava is a rare complication after liver transplantation, but hepatic vein outflow obstruction occurs in 2% to 4% of patients. Restrictions of hepatic blood flow may result from kinking of the suprahepatic cava. This is particularly problematic when the donor is small relative to the recipient and when the suprahepatic anastomosis is left long. Hepatic outflow problems can present with ascites and renal dysfunction. Presentation may be early in the first week after transplantation or months later. The diagnosis may be suspected on the basis of Doppler ultrasonography, but definitive diagnosis usually requires inferior cavography with measurement of pressure gradients. The incidence of caval complications utilizing the piggyback technique appears to be higher than the incidence with the bicaval technique, at approximately 4%.⁶⁶ Outflow stenosis appears to be more common if the combined orifice of two, rather than three, hepatic veins is used for the anastomotic site on the recipient when the piggyback technique is used. In many cases, hepatic vein or suprahepatic caval stenosis can be successfully treated noninvasively with the use of balloon angioplasty and stenting.^{67,68}

Biliary Leak or Stricture

Biliary leak or obstruction is a common surgical complication encountered after hepatic transplantation with an incidence of approximately 10% to 30%.^{53,69} Most biliary complications probably relate to ischemia of the donor biliary tree (Fig. 36.18). The transected donor bile duct is totally dependent on arterial flow from the liver graft. Therefore, when a biliary leak is identified, it is appropriate to interrogate the hepatic vasculature to rule out the presence of hepatic artery stenosis or thrombosis.

Although anastomotic biliary complications can result in mortality from sepsis, they most commonly lead to short-term morbidity. The initial management of biliary complications can

FIGURE 36.18. Bile leak (arrow) from the choledochocholedochostomy after hepatic transplantation.

generally be nonoperative. In most cases, the problem can be both diagnosed and treated by endoscopic retrograde cholangiopancreatography (ERCP). If the biliary reconstruction was made using a Roux-en-Y hepaticojejunostomy, or if ERCP is unsuccessful, biliary leaks must be diagnosed and treated by interventional radiology using percutaneous transhepatic cholangiography and percutaneous placement of a biliary stent. In addition to stenting the anastomosis, it may be necessary to place a percutaneous drain if there is a significant extrahepatic collection of bile. In cases where initial studies show a large defect and in cases where the leak is not controlled through percutaneous measures, operative repair using a Roux-en-Y hepaticojejunostomy may be indicated.

Biliary obstruction resulting from anastomotic strictures can also generally be managed nonoperatively by using percutaneous cholangioplasty or ERCP. When anastomotic strictures persist beyond two attempts at balloon dilatation and stent replacement, operative repair may be an option as long as the entire biliary stricture is extrahepatic and there are no intrahepatic strictures.

While anastomotic strictures are less likely to cause long-term morbidity, intrahepatic biliary strictures, also referred to as intrahepatic cholangiopathy, can be progressive and lead to allograft dysfunction, cholangitis, and, ultimately, either death or retransplantation. Intrahepatic cholangiopathy is largely related to ischemic injuries, occurs in the setting of hepatic artery thrombosis, and occurs in approximately 20% of donation following cardiac death (DCD) liver recipients.

Intra-abdominal Sepsis

Intra-abdominal sepsis presents as diffuse peritonitis or localized abscess and occurs in about 5% of patients who undergo liver transplantation. The most common cause of peritonitis is leakage of the biliary anastomosis. Abscesses may also develop spontaneously in the right upper quadrant or elsewhere in the abdomen. Most isolated infected fluid collections can be managed by percutaneous placement of drains guided by ultrasound or computed tomography (CT) scanning, along with broad-spectrum intravenous antibiotics. Generalized infected ascitic fluid is managed with paracentesis and antibiotics. Surgical drainage may be necessary if leakage of enteric contents is suspected based on the finding of extravasated oral contrast in the peritoneal cavity on CT scan, or if the patient does not respond to percutaneous drainage.

Neurologic Complications

A number of preoperative and postoperative factors predispose to impaired consciousness and seizure activity after transplantation. Patients who have significant preoperative encephalopathy are more likely to suffer from postoperative neurologic symptoms. In the extreme, patients who are in hepatic coma from fulminant liver failure can sometimes take weeks to regain complete consciousness. Patients undergoing liver transplants are also at risk for watershed infarcts if significant intraoperative hypotension occurs. The effects of transient cerebral ischemia are worsened by the large amount of intravenous fluids that are often necessary during and after transplantation, which can exacerbate cerebral edema. Air embolism is also a risk if venous bleeding occurs from the cava or hepatic veins at a time when the patient is relatively hypovolemic. If the patient has a patent foramen ovale, air embolism can result in cerebral ischemia if large bubbles lodge in the cerebral circulation. If the patient fails to awaken promptly after transplantation, and particularly if the transplant is functioning well, an urgent CT scan of the head should be obtained to rule out intracranial hemorrhage and to assess the degree of cerebral edema.

Seizures are reasonably common after transplantation. The calcineurin inhibitors cyclosporine and tacrolimus both lower seizure threshold and are associated with seizures following liver transplantation. Patients with a history of seizures are particularly predisposed to postoperative seizure activity. Seizures are treated with benzodiazepines acutely. The use of many long-term anticonvulsants alter the metabolism of calcineurin inhibitors. Therefore, levetiracetam is often used. To prevent recurrence of seizure activity, it is usually necessary to decrease the dosage of calcineurin inhibitor to a lower target blood level. Frequently it is also necessary to change to a different calcineurin inhibitor altogether, or even to change the patient's maintenance immunosuppression to a regimen that does not include a calcineurin inhibitor.

REJECTION AND IMMUNOSUPPRESSION

- 5** For reasons that are only partly understood, liver transplant recipients require less immune suppression than patients with other types of allografts, such as heart, lung, and kidney recipients. This is somewhat surprising given that the mass of the liver is so great compared with the mass of the other organs. With current immunosuppressive therapy, graft loss from rejection is rare.

Antibody-mediated Rejection

The liver is relatively resistant to injury from recipient antibodies, regardless of whether they are present at the time of transplant or develop later. This is very different compared with renal and cardiac recipients who experience rapid graft destruction, termed *hyperacute rejection*, if performed in a patient who has complement fixing antibodies directed against the donor organ in significant concentrations at the time of transplantation. Hepatic graft injury from preexisting antibodies directed at donor ABO determinants does occur, but in a much less pronounced fashion than in the context of renal transplantation. The overall results of ABO-incompatible liver transplants are somewhat inferior to those of ABO-compatible transplantations, but only by about a 10% to 20% decrease in 1-year graft survival rates compared to ABO-compatible grafts. Some of this decrease in graft survival rate may be due to the fact that ABO-incompatible transplants are usually performed only in dire circumstances where the patient is so ill that he or she may not survive the wait for a compatible organ. Because preformed antibodies do not seem to be clinically important, most transplantation programs do not perform prospective cross matches between recipient serum and donor cells before transplantation, and determination of recipient and donor HLA type is no longer considered mandatory.

Why the liver is less susceptible to antibody-mediated destruction than the kidney is not clearly understood. One factor may be the vastly different microcirculation that the liver has compared with the kidney, with a preponderance of sinusoidal channels and a smaller capillary network. It is probable that antibody-mediated injury affects blood flow through the delicate capillary network of the kidney more than it does liver sinusoids. In addition, each hepatocyte is exposed to two sinusoidal channels, presumably permitting survival if only one sinusoid is occluded. Finally, differences in HLA antigen expression are known to exist in the two organs, with the kidney the more antigenic of the two.

Cell-mediated Rejection

- 6** Typical acute rejection in liver transplant recipients is usually cell mediated and occurs frequently but is effectively blunted

FIGURE 36.19. Acute rejection of a liver transplant. **A:** A portal tract is expanded by a polymorphous inflammatory infiltrate consisting of large and small lymphocytes, plasma cells, macrophages, and neutrophils. The bile ducts (*arrows*) are damaged and inflamed. **B:** A central vein from the same biopsy exhibits endothelitis, characterized by swollen endothelial cells and infiltrating lymphocytes. (Reproduced with permission from Thung SN, Gerber MA. Histopathology of liver transplantation. In: Fabry TL, Klion FM, eds. *Guide to Liver Transplantation*. New York: Igaku-Shoin Medical Publishers; 1988.)

by antirejection therapy. Acute rejection occurs most commonly in the first 2 postoperative months. In modern practice, cell-mediated rejection is a less common cause of graft loss than is primary nonfunction or hepatic artery thrombosis. Still, the effectiveness of antirejection treatment assumes a relatively early diagnosis and treatment of acute rejection, which is in turn the result of careful monitoring by the transplantation physician and compliance by the patient with frequent laboratory testing. Treatment of acute rejection with enhanced immunosuppressive therapy is highly effective, and an episode of rejection does not affect long-term graft survival. This is very different from renal transplantation, where an episode of rejection decreases long-term graft survival markedly.

The diagnosis of cell-mediated rejection is made primarily on a histologic basis. Clinical features can include low-grade fever and malaise, but frequently the patient is completely asymptomatic. Laboratory evaluation of peripheral blood may demonstrate leukocytosis and occasionally eosinophilia. Biochemical changes associated with rejection include elevated and rising levels of serum transaminases and alkaline phosphatase. A prolonged serum prothrombin time and an abnormal serum bilirubin also suggest the possibility of rejection, but frequently these parameters are normal if rejection is detected early. Any of these findings should prompt a biopsy.

The diagnosis of cell-mediated rejection rests on the finding of a triad of portal lymphocytosis, endotheliitis (subendothelial deposits of mononuclear cells), and bile duct infiltration and damage (Figs. 36.19 and 36.20). Various classification schemes have been devised to grade the severity of the rejection process based on the degree of cellular involvement or injury in these areas. Cell characterization studies have documented that the cells in the portal triads are primarily T cells, with fewer macrophages and neutrophils. Bile duct epithelial cells appear to be a prime target of immune attack, and they are known to express large amounts of class II HLA antigen.

If the recipient has hepatitis C, it is critical that recurrent hepatitis C is differentiated from acute rejection. At times the difference can be subtle, and a pathologist with experience in the interpretation of allograft biopsies is extremely valuable. Enhanced immunosuppression is associated with accelerated rates of hepatitis C viral replication; it is, therefore, important that immunosuppression is kept to a minimum for these patients.

Chronic Rejection

- 7 Chronic rejection is characterized by relentless immune attack on small bile ducts. Clinically, the pattern is one of gradual elevation of alkaline phosphatase and bilirubin, in the absence of obstruction of the large bile ducts. Histologically, small bile ducts are obliterated or completely absent, with a less pronounced cellular infiltrate than is seen with acute rejection. This finding has been termed *vanishing bile duct syndrome* when bile ducts are absent in 15 of 20 portal triads examined.⁷⁰ The loss of small bile ducts is partly the result of lymphocyte-directed attack on biliary epithelium. Relative to other cells in the liver, biliary epithelium tends to express more class I antigen. Thus, biliary epithelial cells are vulnerable targets for host attack because of their antigenicity. Loss of bile ducts may also occur indirectly as the result of ischemia

FIGURE 36.20. Arterial lesion of chronic hepatic rejection. Subintimal foam cells, intimal sclerosis, and myointimal hyperplasia obliterate the arterial lumen. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

secondary to immune-mediated obliteration of small to medium arteries. As in the case of renal transplantations, there is no effective treatment for chronic rejection except retransplantation.

Immunosuppression Induction and Maintenance

Multiple immunosuppressive protocols achieve acceptable suppression of allograft rejection for liver transplant recipients. Induction with antithymocyte globulin is no longer considered to be mandatory but is used at some centers. Similarly, prednisone therapy, once considered a mainstay of a successful immunosuppressive protocol, is no longer considered absolutely necessary and when used is often tapered rapidly. Treatment with a calcineurin inhibitor, either cyclosporine or tacrolimus, is still considered to be imperative for most liver transplant recipients. These agents are associated with significant long-term morbidity, particularly the development of chronic renal failure. Dosages of these agents have gradually been reduced both to prevent renal insufficiency and to avoid the rapid and aggressive recurrence of hepatitis C infection. Induction antibody therapy with either polyclonal antilymphocyte preparations or with inhibitors of the receptor for interleukin 2 is still used commonly in the perioperative setting to avoid the nephrotoxicity associated with the immediate use of calcineurin inhibitors.

Because immunosuppression predisposes to infection, prophylactic anti-infective drugs are usually administered. Trimethoprim-sulfamethoxazole, dapsone, or pentamidine is recommended to prevent *Pneumocystis carinii* infection. Oral Mycostatin or fluconazole therapy is used to prevent fungal infections, particularly esophageal *Candida albicans*. Either ganciclovir or valganciclovir is prescribed for patients who are at risk for CMV infection, which includes any patient exposed to CMV in the past and any patient transplanted with organs from a donor who has been exposed to CMV. Patients who are CMV negative who receive CMV-negative organs are not at risk for CMV infection but should still receive prophylaxis against disseminated herpes simplex infections with acyclovir therapy. The duration of prophylactic anti-infective therapy has not been rigorously defined by evidence-based trials and is therefore dependent on each center's experience with the prevalence of these infections in its patient population.

Treatment of Acute Rejection

Despite the overall effectiveness of the regimen described, acute rejection does occur and must be treated promptly. Several options are available for treatment of acute rejection, depending on the clinical circumstances. Traditionally, high doses of methylprednisolone are administered (usually 500 mg to 1 g) intravenously on a daily basis for 3 days. This treatment is effective in reversing most acute rejection episodes. Alternatively, increased doses of a calcineurin inhibitor or the addition of an antimetabolite drug, such as mycophenolate mofetil, will also reverse most episodes of rejection, particularly if the rejection is mild. Rejection that is resistant to these maneuvers is treated with antilymphocyte therapy, either a monoclonal antibody directed at the T3 determinant common to all mature T cells (Orthoclone, OKT3) or polyclonal antilymphocyte treatments such as Atgam or thymoglobulin. These treatments are typically administered daily for 5 to 10 days. These agents are highly effective, and it is unusual to lose an allograft secondary to acute rejection. However, these treatments are associated with profound and long-lasting immunosuppression, and it is usually advisable to restart prophylactic anti-infective therapies when they are initiated.

RESULTS

- 8** The patient survival rate following liver transplantation in the United States at 1 year is more than 85% for adults and nearly 90% for children. Patients who survive the first year following a liver transplantation experience approximately a 3% annual mortality rate thereafter, so 3-year survival rates for adults and children are currently 78% and 83%, respectively.

The most important predictors of survival following liver transplantation are whether the patient has previously undergone transplantation and whether the patient was in the intensive care unit at the time of transplantation. Although not as important as the condition of the patient at transplantation, the cause of liver failure is also an important determinant of success. Five-year survival varies from approximately 60% for patients transplanted for malignancy to 70% for patients transplanted for viral and alcoholic cirrhosis. The best 5-year survival rates of around 80% are seen with patients transplanted for metabolic liver disease, biliary atresia, and cholestatic liver diseases (primary biliary cirrhosis and primary sclerosing cholangitis).³⁷ The volume of liver transplants performed at a given transplant center is also associated with patient survival, with higher-volume programs exhibiting higher adjusted overall patient survival rates.⁷¹

CHAPTER 37 ■ CARDIAC TRANSPLANTATION

RICHARD N. PIERSON III

KEY POINTS

- 1 Over the past 50 years, heart transplantation has evolved from public spectacle to accepted therapeutic modality based on improved tools to diagnose rejection and infection and an expanded armamentarium of treatment options.
 - 2 Heart transplantation is offered to patients for whom no other reasonable treatment options exist and who are at higher risk of death without transplant than with it, while excluding those whose comorbid conditions are likely to significantly limit length or quality of life.
 - 3 The mortality rate for patients awaiting transplant has improved significantly over the past decade due to improvements in (a) patient selection, (b) medical therapy of patients awaiting transplantation, (c) mechanical support as a bridge to transplant, and (d) donor management and allocation algorithms.
 - 4 Of the four techniques for performing heart transplantation, orthotopic transplant using bicaval right atrial connections has emerged as the most popular.
 - 5 A “triple-drug” regimen including a calcineurin inhibitor, an antimetabolic agent, and a steroid, with or without anti-lymphocyte “induction,” is employed to prevent graft injury due to acute rejection.
 - 6 Prophylaxis against opportunistic infections includes agents targeted at common bacterial, viral, and protozoal pathogens.
 - 7 Although the number of heart transplants performed worldwide has declined due to a donor organ shortage, operative survival has improved over the past 20 years, and both patient and graft 1-year survival rates exceed 87% for adults.
 - 8 Rejection and infection together account for most of the mortality during the first year, whereas long-term survival is limited by cardiac allograft vasculopathy (a manifestation of chronic rejection) and malignancy.
 - 9 Current initiatives in the field include development of improved immunosuppression (perhaps leading to graft “tolerance”) and alternatives to heart allotransplantation, such as “destination” mechanical support or heart xenografts from genetically modified pigs.
- 1 Since 1964, cardiac transplantation has evolved from a sensational, perilous experiment to become conventional therapy for end-stage heart disease, the paradigm of successful but expensive “high-tech” medicine. This remarkable transformation stemmed from fundamental surgical innovations supported by incremental improvements in the diagnosis and management of common problems. Current challenges revolve around donor supply and allocation, improving long-term outcomes, developing alternative therapies, and related ethical issues.

HISTORICAL PERSPECTIVE

Based on significant contributions by many surgical pioneers,^{1–8} the first clinical heart transplant was performed in 1964 by Hardy, who attempted to salvage a man dying from cardiogenic shock by replacing his heart with one from a chimpanzee.⁹ Then, before the concept of brain death achieved wide social or legal acceptance, in 1967 Christian Barnard et al. captured the imagination of the world with the first operative survival, using the heart of a resuscitated cadaveric donor.¹⁰ This case, and many others that were performed shortly thereafter, demonstrated not only the physiologic capacity of the transplanted human heart allograft to support the recipient's circulation but also the difficulty of managing subsequent immunologic and infectious complications. After a worldwide flurry of activity, generally dismal outcomes at many prominent cardiac surgery centers made clear the need for more thoughtful approaches to what was clearly a difficult constellation of problems beyond effective circulatory support.

A few pioneering programs persisted in cautious clinical application supported by parallel laboratory investigation. Recognizing the need for a more sensitive and specific diagnostic technique to diagnose rejection, Phillip Caves, working

with Shumway et al. at Stanford, developed the technique of transvenous endomyocardial biopsy.¹¹ Frequent, representative surveillance sampling of the graft allowed early detection of pathogenic host immune responses. Perivascular lymphocytic infiltrates were found to accurately diagnose acute cellular rejection in its presymptomatic phase; when detected early, rejection usually responded to enhanced immunosuppression. Equally important, when rejection was not seen, immunosuppression could be tapered to minimize drug toxicities and reduce the incidence of opportunistic infection. Coupled with important advances in the diagnosis, prevention, and treatment of infectious pathogens in immunosuppressed patients and in selection and management of patients with end-stage heart failure, patient survival at 1 year improved gradually, from about 20% in the 1960s to about 70% by 1980.¹²

However, even as recently as the early 1980s, when rejection persisted or recurred despite high-dose steroids, alternative treatments (total lymphoid irradiation, intramuscular antilymphocyte preparations, thoracic duct ligation, splenectomy) were often toxic or invasive and accompanied by a high incidence of major short- and long-term complications. In this context the discovery and clinical development of cyclosporin A^{13,14} catalyzed the next major improvement in outcomes. Because the primary mechanism of action (inhibition of calcineurin-dependent cellular activation events) and toxicity profile were fundamentally different from those of azathioprine, an antimetabolic agent, or anti-inflammatory steroids, combination “triple” therapy allowed each agent to be used more safely. Meanwhile, antithymocyte and antilymphocyte preparations were adapted for safe intravenous use, either as prophylactic induction therapy (“quadruple therapy”) or as treatment for steroid-resistant rejection. Based primarily on these pharmacologic innovations in the regulation of the immune response, expected 1-year survival following heart

transplant gradually rose from about 70% to almost 88% between 1980 and 2008 despite increasing reliance on older donors for older and sicker recipients.^{15,16}

CANDIDATE EVALUATION

End-stage heart failure is the primary indication for heart transplantation in adults, with coronary artery occlusive disease and myopathy of various etiologies each accounting for about 45% of cases. Congenital heart disease is the primary indication for infants, whereas myopathy predominates in older children.

- 2** The heart transplant evaluation process seeks to identify patients for whom no other reasonable treatment options exist and who are at higher risk of death without transplant than with it, while excluding those whose comorbid conditions are likely to significantly limit length or quality of life. In 1993, a National Institutes of Health consensus conference developed recipient selection guidelines for cardiac transplantation, based on objective criteria known to predict poor outcome without transplantation¹⁷; these guidelines (Tables 37.1 through 37.3) continue to evolve in the context of improving heart failure therapy.^{18–20} Among patients with heart failure symptoms, maximal oxygen consumption (MVO₂) is more sensitive and specific than ejection fraction in gauging prognosis, and blunted cardiac output response to exercise may further stratify patients into high- and low-risk groups.¹⁸

When no clear survival advantage is apparent for transplantation or an alternative management strategy, quality of life and other subjective factors are weighed. Contemporary studies defining relative risks, along with basic considerations in the medical management of end-stage heart failure, are well summarized in recent reviews.^{19,20}

TABLE 37.1

INDICATIONS FOR HEART TRANSPLANT

General indications

- End-stage heart disease without lower-risk alternative
- Absence of any noncardiac condition likely to:
 - 1) limit survival independent of cardiac function
 - 2) preclude safe administration of adequate immunosuppression
 - 3) predispose to life-threatening infection with immunosuppression

Specific indications

- 1) Heart failure of various etiologies
 - a) Myopathy: ischemic, idiopathic, viral, familial, restrictive
 - b) Valvular
 - c) Congenital
 - d) Failed transplant
 - Early: Primary nonfunction, acute rejection
 - Late: Cardiac allograft vasculopathy
- 2) Other indications
 - a) Angina not amenable to revascularization
 - b) Arrhythmia, failed conventional therapy
 - c) Hypertrophic cardiomyopathy
 - d) Restrictive cardiomyopathy
 - e) Primary cardiac tumor (completely resectable)

TABLE 37.2

SELECTION CRITERIA FOR STRATIFYING RISK AND SURVIVAL RESULTS

Survival benefit established

- MVO₂ <10 mL/kg/min
- Class IV CHF symptoms despite maximal medical therapy
- Requiring mechanical circulatory support
- Refractory angina without therapeutic alternative
- Refractory ventricular arrhythmia without alternative

Survival benefit likely

- MVO₂ 10–14 with blunted CO response to exercise
- Instability of fluid balance or renal function despite documented compliance
- EF <20% with class III HF symptoms on maximal medical therapy

Survival benefit not established

- MVO₂ 10–14 with preserved CO response to exercise
- MVO₂ >14, EF <20% without other indication
- History of CHF or arrhythmia, controlled with medical therapy
- Quality-of-life considerations may influence selection of recipients for whom survival benefit is not established.

CHF, congestive heart failure; CO, carbon monoxide; EF, ejection fraction; MVO₂, maximal oxygen consumption.

DONOR SELECTION AND MANAGEMENT

The ideal donor is a young, previously healthy individual without cardiac disease or hypertension, who is well matched in size to the intended recipient and whose hemodynamics have been carefully managed during the evolution of his or her lethal central nervous system (CNS) injury. Some programs have advocated use of older donors, donors who may transmit infection or malignancy to the recipient, and grafts with hypertensive myocardial hypertrophy for particular recipients.²¹ Some aggressive programs have even proposed that hemodynamically significant coronary stenoses can be bypassed at the time of transplant.²² These approaches to donor selection are associated with less favorable short- and long-term outcomes,^{15,23,24} but the increased risk may be considered acceptable for patients in whom the short-term prognosis is poor without transplant.

Donor management requires skill and experience to successfully address the complex physiologic perturbations associated with brain death. Reflex hypertensive and hypotensive responses to intracranial pressure changes, fluid and electrolyte imbalances consequent to the diabetes insipidus from pituitary death, and additional stresses related to hemorrhage, trauma, and surgery often cause hemodynamic and metabolic instability, which may injure a previously healthy heart. The neurohumoral milieu of CNS catastrophe may also adversely affect other fundamental cell regulatory functions, such as those dependent on thyroid hormone. Despite controversy regarding the mechanisms involved, thyroid hormone is often administered to the donor as a continuous infusion, hoping to correct a “sick euthyroid” syndrome and optimize cardiac metabolism prior to explant. Although evidence to date is largely anecdotal, inotrope requirements can often be reduced after thyroid infusion is begun, and donor hemodynamic

TABLE 37.3**CONTRAINDICATIONS TO CARDIAC TRANSPLANTATION****Absolute contraindications**

- High pulmonary vascular resistance^a
 - Transpulmonary gradient >15, fixed
 - Pulmonary vascular resistance index >5–6 Woods Units
- Irreversible renal insufficiency (CrCl <40)^a
- Active infection (viral or bacterial)
- Active peptic ulcer disease
- Diabetes with end-organ damage, renal insufficiency, neuropathy, retinopathy
- Symptomatic extracardiac vascular disease
 - CVOD with recent TIA, CVA
 - PVOD with claudication, rest pain, or tissue loss
- Current malignancy or recent treatment (<2 y) for life-threatening malignancy
- Disease of another organ system that would probably limit survival
 - Established cirrhosis, cardiac or other etiology
 - Symptomatic COPD; chronic bronchitis
- High risk for inability to comply with complex medical regimen
 - Not firmly committed to transplantation
 - Inadequate cognitive capacity to comply with postop regimen, coupled with inadequate compensatory social support
 - Documented psychiatric instability
 - Recurrent drug or alcohol abuse
 - Demonstrated noncompliance with therapeutic recommendations

Relative contraindications

- Age over 65
- Established renal failure
- Diabetes without end-organ disease
- Asymptomatic or previously treated extracardiac vascular disease
- COPD with FEV₁ or DLCO <60% predicted without referable symptoms
- Remote malignancy, in remission (>4 y with no evidence of disease)
- High pulmonary vascular resistance, reversible
- Disease of another organ system that would limit quality of life
- Difficulty complying with complex medical regimen

COPD, chronic obstructive pulmonary disease; CrCl, creatinine clearance; CVA, cardiovascular accident; CVOD, cerebrovascular obstructive disease; DLCO, carbon monoxide diffusing capacity; FEV₁, forced expiratory volume in 1 second; PVOD, pulmonary veno-occlusive disease; TIA, transient ischemic attack.
^aOn optimal medical therapy.

lability is less common, suggesting improved cardiac and vasoregulatory function.^{25,26}

Cardiac echocardiography has become a standard component of donor assessment to measure ejection fraction and to exclude structural abnormalities or hypertrophy suggestive of hypertensive myopathy. Cardiac catheterization may be requested for donors over age 45, especially for those with a

strong family history of coronary artery disease, for smokers, or when regional wall motion abnormalities are appreciated on echocardiography.

MATCHING DONOR TO RECIPIENT

Once a potential donor is identified, priority among blood type-compatible recipients is determined first by relative severity of illness (“status”) and then by length of time on the waiting list among those at each status in the donor’s geographic area. In the United States, this information is currently tracked and collated by a central, national registry operated by the United Network for Organ Sharing. The heart is first offered to the program whose candidate has priority on the list and whose registered height and weight range include the potential donor. Donor inotrope requirements and functional assessment, recipient pulmonary vascular resistance, possible infection transmission risks (known hepatitis or potential human immunodeficiency virus [HIV] exposure in the donor), and other logistical considerations (expected graft ischemic time) influence the recipient team’s decision regarding acceptance of an organ for an individual patient. If the first program declines the offer for the first patient, the process is repeated for the patient next on the list until the heart is accepted.

Tissue typing, the time-consuming process by which donor and recipient are matched for shared transplant antigens, is not currently used for hearts. The probability is low of identifying a “close” match among the relatively small number of blood type-compatible potential recipients within the geographic radius (usually <1,500 miles) defined by a 4-hour projected ischemic time. In addition, the demonstrated benefit of partial human leukocyte antigen (HLA) matching is small relative to the added risk of prolonged graft ischemia, a risk augmented by increasing donor age.^{16,27}

RECIPIENT MANAGEMENT BEFORE TRANSPLANT

- 3 The medical therapy of patients awaiting transplantation has improved significantly over the past decade, centered around aggressive afterload reduction and diuresis, anticoagulation, and beta blockade.^{18–20} This trend, coupled with improved mechanical support and improved donor allocation algorithms (discussed later), has reduced the mortality rate for patients awaiting transplantation. As waiting lists have grown faster than the donor pool and average time waiting has similarly escalated, cardiac decompensation among patients on the waiting list is frequent. In most areas of the United States and Europe, the majority of hearts go to patients who are sick enough to require hospitalization for intensive diuresis and intravenous inotrope administration.^{15,16}

When inotropic therapy proves inadequate, as gauged by progressive deterioration in renal and other end-organ function, temporary intra-aortic balloon pump counterpulsation and mechanical ventilation can stabilize some patients. These interventions are associated with important risks; the relative risk of death is increased threefold in patients who are ventilator dependent at the time of transplant.^{15,16}

In contrast, mechanical circulatory support using ventricular assist devices has emerged as an effective bridging strategy. Although some bridged patients incur serious complications (stroke, renal or hepatic failure, systemic infection) that preclude transplantation, about three quarters are successfully transplanted, with excellent outcomes relative to patients not requiring this intervention.¹⁶ Patients with biventricular failure can be supported with either implanted or paracorporeal

pulsatile left ventricular support, with or without addition of temporary right heart support. Various total artificial heart devices can be implanted in place of the native heart and have been applied successfully in small numbers.²⁸ This approach is most likely to find a niche as an alternative to heart transplantation in patients not supportable with a left ventricular assist device, such as those with fixed pulmonary hypertension. Intravascular axial flow devices and other nonpulsatile assist systems have shown promise in clinical trials.^{29,30}

HEART PROCUREMENT

Cardiac allograft protection depends primarily on hypothermia, which reduces myocardial energy requirements while the heart graft has no nutritive coronary blood flow. Other important principles include avoidance of distention and warm ischemia in both the donor and the recipient and induction of diastolic (flaccid) cardiac arrest. These goals are accomplished by interrupting systemic venous return for decompression, placing a clamp across the distal ascending aorta, and infusing a hyperkalemic preservation solution proximal to the clamp, and thus selectively into the coronary arteries. Both the inferior vena cava and left atrium are incised ("vented") to prevent distention of either ventricle. Some preservation solutions incorporating free radical scavenging molecules or other cytoprotective agents are associated with improved early graft function.^{31,32}

Every effort is made to limit the ischemic interval, the time between initial interruption of coronary flow by aortic cross-clamping in the donor and removal of the cross-clamp in the recipient, to less than 4 hours. Although laboratory studies and isolated clinical reports suggest that good results may be expected with storage times of 8 hours or more using various preservation solutions, increased ischemic time remains a strong and important independent risk factor for poor recipient outcome.^{15,16}

OPERATIVE RECIPIENT MANAGEMENT

Timing of the recipient operation requires careful coordination with the procurement team. Anesthesia is induced after the donor heart is visually inspected and found suitable. Venous access is obtained, which will permit rapid volume resuscitation and invasive cardiac monitoring after the new heart is implanted. Prior cardiac surgery may complicate coordination of operative timing and is associated with increased risk of bleeding.

If appropriate, Coumadin effects are reversed with fresh frozen plasma and vitamin K. Aprotinin or ϵ -aminocaproic acid are often used to inhibit fibrinolysis and prevent coagulopathic bleeding after prior cardiac surgery or associated with hepatic congestion. Increased inotropic infusion, antiarrhythmic agents, or mechanical circulatory support may be required

FIGURE 37.1. Native cardiectomy and donor graft preparation. **A:** Recipient pericardium after institution of cardiopulmonary bypass and ascending aortic occlusion, with caval snares secured. The diseased native heart can then be safely excised by transecting the recipient aorta and pulmonary artery, and the atria divided as appropriate for the intended implant technique. Shown is the right atrial incision for the traditional Lower/Shumway right atrial cuff. **B:** Posterior view of the explanted donor heart, indicating various incisions used for atrial cuff preparation. Donor atrial cuff incisions made in preparation for traditional Lower/Shumway biatrial implant are indicated by the heavy white dashed line. The superior vena cava (SVC) is ligated or oversewn. Right and left pulmonary vein (light white dashed line) and superior vena cava (black dashed line) incisions are indicated for the total atrioventricular implant technique. For the bicaval technique, the donor SVC (black dashed line) and inferior vena cava are retained as for the total atrioventricular technique (Fig. 37.4), and the donor left atrial cuff trimmed as for the traditional biatrial approach (heavy white dashed line).

FIGURE 37.2. Traditional Lower/Shumway biatrial technique. **A:** Recipient cuffs, prepared for bicaval atrial implant technique. After completion of the left atrial anastomosis (**B**), the right atrial cuffs are joined. Care is taken to avoid carrying the right atrial incision or suture line close to the donor sinoatrial node, at the superior vena cava/right atrial junction (*asterisk*). **C:** Appearance of the operative field after completion of great vessel anastomoses, weaning from cardiopulmonary bypass, and decannulation.

to maintain adequate systemic perfusion prior to institution of cardiopulmonary bypass.

Vascular access for bypass is accomplished by cannulation of the superior and inferior vena cavae so as to completely divert systemic venous blood to the cardiopulmonary bypass circuit. The ascending aorta, common femoral, or subclavian artery is used for arterial return from the circuit to the patient. Technical misadventures, such as entry into the heart or great vessels before bypass is established or induction of ventricular arrhythmias, are more common with reoperative procedures and can greatly complicate the intraoperative course and postoperative management.

Once the proximate arrival of the donor heart is ensured, the recipient is placed on bypass and cooled. Snares are secured around the caval cannulae, the ascending aorta clamped, and the native heart excised (Fig. 37.1A). Vascular cuffs are preserved, which are appropriate for implantation of the donor heart (Figs. 37.2A, 37.3A, and 37.4A). The donor heart is then prepared according to the implant technique to be used (Fig. 37.1B).

Implant techniques and the sequence of vascular anastomosis vary widely between surgeons, as do strategies used to protect the ischemic organ during implantation. The biatrial orthotopic heart transplant technique is simple, easy to teach, and still used by many surgeons⁸ (Fig. 37.2A–C). The donor atria are spatulated open, trimmed if necessary, and laid over the recipient's atrial remnants. The left atrial suture line is everted to achieve endothelial apposition and to avoid leaving

epicardial fat or muscle exposed in the lumen as a potential nidus for thromboemboli. Sinoatrial node dysfunction can usually be prevented by keeping the donor right atriotomy well anterior on the right atrial appendage, away from the sinoatrial node and its blood supply (Fig. 37.2B), and by optimizing graft preservation.³² Even if most of the dilated native atrium is excised, atrioventricular (AV) valve annular geometry may be distorted, causing regurgitation, or the area around the sinus node may be placed under tension, leading to atrial arrhythmias or sinus node dysfunction.

During the 1990s, these considerations led to evaluation of alternate atrial anastomotic techniques, including bicaval right atrial connections (Fig. 37.3A–C) and total atrioventricular replacement (two caval and two pulmonary vein anastomoses) (Fig. 37.4A, B). In a prospective, randomized trial (bicaval³³) and several retrospective analyses,^{34,35} the incidence of atrial arrhythmias and AV valve regurgitation was reduced, and hemodynamic results and survival were improved with either the bicaval or total atrioventricular technique.

Independent of whether the aorta or pulmonary artery connection is performed first, the anterior aspect of the pulmonary artery anastomosis is usually left open or vented, to allow decompression of the right heart after reperfusion (Fig. 37.3C). The size mismatch between donor and recipient aortas is often dramatic, but can usually be accommodated by beveling the smaller vessel (usually the more pliable donor) to increase its effective circumference and by distributing the discrepancy evenly over the length of each anastomosis. Occasionally it is

FIGURE 37.3. Bicaval right atrial implant technique. **A:** During explantation of the native heart, the interatrial septum may be excised, for end-to-end anastomosis of the cavae (**B**), or left in place (as in Fig. 37.2A), allowing the back walls of the donor cavae to be laid into those of the recipient. **C:** Technique for pulmonary artery venting through an opening in the anterior aspect of this anastomosis, which is useful for deairing and decompressing the right heart. Alternatively, the aorta may be anastomosed earlier in the operation to minimize graft ischemic time.

necessary to tailor down the larger vessel or to replace an aneurysmal ascending aorta with donor tissue or a prosthetic graft. Functional pulmonary stenosis is avoided by trimming back both donor and recipient sufficiently to prevent redundancy.

An alternate “heterotopic” implantation technique places a second heart in the circulation, in parallel with the retained native heart.³⁶ In principle, leaving the native heart affords protection in the event that the graft fails. The operation is technically demanding, usually produces compressive atelectasis in the right lung, and is associated with a high risk of stroke, perhaps due to stasis of blood in the native heart.³⁷ Notwithstanding, this surgical approach may be considered for patients with high pulmonary vascular resistance unresponsive to vasodilators, and may in the future also find a role in the initial application of cardiac xenografts.

After completion of the anastomoses, the heart is reperfused and allowed to resume contracting without being required to function as a pump (“rested”) as the recipient is rewarmed. Atrial and ventricular pacing wires are placed. Cardiac output of the denervated transplant is highly dependent on rate. In addition, the shorter cardiac filling time associated

with higher heart rate prevents graft distention. Isoproterenol is initiated prior to weaning from bypass at a dose of 0.005 to 0.02 $\mu\text{g/kg}$ per minute and titrated to achieve a heart rate of about 110 beats per minute.

Patients with high preoperative pulmonary vascular resistance may be particularly difficult to wean from cardiopulmonary bypass, even with excellent function of the donor heart, as the “normal” donor right ventricle may acutely dilate and fail when confronted by a high-resistance pulmonary vascular bed. Resting the recently ischemic heart on cardiopulmonary bypass, establishing a stable sinus or AV sequentially paced rhythm, instituting inotropic support, and intra-aortic balloon counterpulsation are useful in managing this problem. Traditional pharmacologic approaches to reducing pulmonary vascular resistance, such as prostaglandins E_1 or I_2 and sodium nitroprusside, may cause transpulmonary shunting of deoxygenated blood; these agents also reduce systemic vascular resistance and thus coronary perfusion pressure. Inhaled nitric oxide selectively dilates the pulmonary vascular bed before being rapidly inactivated by hemoglobin in the blood. We and others have found this very helpful to selectively reduce pulmonary vascular resistance without adverse effects on oxygenation or heart

FIGURE 37.4. Total atrioventricular transplant technique. **A:** Recipient pericardial well after preparation of bilateral pulmonary vein pedicles and caval cuffs, for total atrioventricular heart transplant. **B:** Construction of left pulmonary vein anastomosis. As with other left atrial anastomotic approaches, atrial walls or vein cuffs are everted to minimize exposure of thrombogenic fat or muscle to the blood.

function, and this drug has recently been approved by the U.S. Food and Drug Administration for clinical use.³⁸ Poor function of either or both ventricles may necessitate institution of mechanical support as a bridge to graft recovery or to retransplantation.

Postoperatively, ventilator and inotropic support is weaned, immunosuppression is instituted, and diuretic and antihypertensive agents are initiated as necessary. Isoproterenol is continued for about 5 days and replaced with theophylline if needed to sustain a resting heart rate over 70. The first surveillance endomyocardial biopsy is performed 7 to 10 days after surgery and repeated as an outpatient procedure about every 2 weeks for the first 3 months. Patient and caregiver education with regard to medication schedules and physiologic monitoring facilitates early discharge for patients without complications. Biologic monitoring of peripheral blood gene or protein expression and electrical approaches to monitor the immune response to the graft have shown promise to supplant routine invasive monitoring.^{39–41}

IMMUNOSUPPRESSION

5 The goal of immunosuppressive therapy is to prevent immune-mediated injury to the graft while minimizing associated complications, including opportunistic infection. Most programs employ a “triple-drug” regimen, including a calcineurin inhibitor, an antimetabolic agent, and steroids. This approach allows each individual drug to be used within its therapeutic window (Table 37.4). Some centers add antibody “induction” with anti-CD3, polyclonal antilymphocyte serum, or anti-interleukin-2 (anti-IL-2) receptor antibodies.^{42–47} The mechanisms of action and side effect profiles of these agents are well described in an earlier section of this chapter.

Medical management after heart transplantation is focused on anticipation and prevention of common complications.

Hypertension and hyperlipidemia are prevalent due to predisposition in the recipient patient population and as side effects of various immunosuppressive agents. Prophylaxis against opportunistic infections includes agents targeted at common protozoal and viral pathogens (Table 37.4). Surveillance biopsies are performed according to a scheduled routine, and additional biopsies are performed to exclude rejection in the event of hemodynamic instability or unexplained fever. Typically, patients are able to leave the hospital within 10 days of uncomplicated operation, to be followed regularly in outpatient clinic. Monitored physical rehabilitation facilitates optimal cardiovascular and musculoskeletal recuperation,⁴⁸ and occupational rehabilitation may offer important psychological and social benefits.

COMPLICATIONS

Complications of antirejection therapy relate primarily to the side effects of the specific immunosuppressive agents currently used. Infections tend to occur in patients with the greatest degree of preoperative debility and malnutrition, or in conjunction with additional stressors such as perioperative bleeding or hepatorenal dysfunction. Bacterial pathogens are common in the first several weeks, particularly in the lung and related to surgical or vascular access sites. Opportunistic viral and fungal infections usually predominate later. Increasingly effective prophylaxis for cytomegalovirus and herpes infections has markedly reduced the morbidity associated with these common pathogens. When infection occurs, immunosuppression is tapered as aggressively as possible based on myocardial biopsy results.

Acute rejection occurs in the majority of patients and is graded histologically according to standardized criteria developed by the International Society for Heart and Lung Transplantation (ISHLT). When detected at an early histologic stage

TABLE 37.4**TYPICAL IMMUNOSUPPRESSIVE PROTOCOL AND ASSOCIATED MEDICAL TREATMENT FOLLOWING ADULT HEART TRANSPLANTATION**

Calcineurin inhibitors:	Cyclosporine	2–4 mg/kg PO bid or 1–4 mg/h IV
	FK506	0.025–0.15 mg/kg PO bid
Side effects:	Hypertension, renal insufficiency, tremor, Hirsutism (cyclosporine A only), gingival hyperplasia, diabetes (FK only)	
Antimitotic agents:	Azathioprine	1–2 mg/kg/d qd
	Mycophenolate mofetil	500–1,500 mg/d bid
Side effects:	Marrow suppression, nausea, abdominal cramps, diarrhea	
Glucocorticoids:	Methylprednisolone IV, then Prednisone PO	
Side effects:	Hypertension, insulin resistance, osteoporosis, mood swings Central obesity, Cushingoid habitus	
Antiprotozoal:	Trimethoprim-sulfamethoxazole (<i>Pneumocystis</i> ; toxoplasmosis)	
Antiviral:	Acyclovir (herpes) Ganciclovir (cytomegalovirus)	
Antihypertensives:	Angiotensin-converting enzyme (ACE) inhibitor or ACE-receptor blocker Diltiazem (retards cyclosporine A metabolism, reducing drug requirement) α -Receptor blockers	
Antilipid agents:	Statin class agent	

(ISHLT grade 1, Fig. 37.5) in an asymptomatic patient on surveillance biopsy, rejection will often respond to augmented oral steroids and/or an increased dose of calcineurin inhibitor. When a higher grade of rejection is found (Fig. 37.6), when the infiltrate fails to resolve in response to initial interventions, or in the setting of depressed cardiac function or shock, high-dose intravenous steroids are administered and antilymphocyte therapy often added. Inotropic or mechanical support is instituted as needed in hopes of rescuing graft and patient. Antibody-mediated “vascular” rejection is a controversial entity that, when documented by immunohistochemical techniques, may warrant introduction of cyclophosphamide or other agents with increased activity against B cells.

FIGURE 37.5. International Society for Heart and Lung Transplantation grade 1R—diffuse interstitial or focal perivascular infiltrate with rare or absent myocyte damage is characteristic of mild acute cellular rejection.

Bradycardia is prevalent in the denervated heart for the first weeks after transplant, but a resting heart rate over 70 can usually be achieved by initiating a β -agonist such as theophylline. Persistent bradycardia may be caused by ischemic, surgical, or immunologic injury to the sinus or AV nodes or by amiodarone leaching from stores accumulated preoperatively in body fat; pacemaker implantation may be necessary. Atrial flutter or fibrillation may occur spontaneously or herald acute rejection. This dysrhythmia can be difficult to manage because vagal denervation attenuates digoxin modulation of the

FIGURE 37.6. International Society for Heart and Lung Transplantation grade 3R—multifocal cellular infiltrate with focal myocyte necrosis, typical of severe acute cellular rejection.

FIGURE 37.7. Autopsy specimen of an epicardial coronary artery demonstrating a moderately severe concentric fibroproliferative intimal lesion characteristic of cardiac allograft vasculopathy. (Courtesy of Dr. James Atkinson, Vanderbilt University School of Medicine, Nashville, TN.)

typical rapid ventricular response. Most other agents traditionally used to treat atrial arrhythmias depress AV node conduction or myocardial contractility, particularly undesirable side effects in a recent heart recipient. Amiodarone is generally better tolerated, controls heart rate and promotes conversion to sinus rhythm, and has been used widely in this circumstance.

Among patients who survive beyond the first year, the primary limits to long-term survival are cardiac allograft vasculopathy (CAV) and malignancy^{15,16,24} (Fig. 37.7). Current understanding of the pathogenesis of CAV is incomplete.^{49–51} Widely presumed to be a consequence of “chronic rejection,” this process has an incidence of approximately 5% per year. CAV may cause progressive insufficiency of coronary flow, myocardial infarction, and ultimately death. Recent research has drawn attention to the importance of donor stress associated with brain death and ischemia/reperfusion injury in the incidence and severity of CAV in animal models.⁵² In contrast to the usual pattern of focal proximal lesions in conventional atherosclerosis, coronary arteries are diffusely involved, and conventional revascularization techniques are not generally feasible. In the future, new immunosuppressive or antiproliferative agents may prevent this process or delay its progression.⁵³ Both CAV and increased risk of malignancy would likely be prevented if efforts to accomplish durable tolerance are successful, but this obstacle is proving stubborn.⁵⁴

RESULTS

- 7** Due to a decline in the number of donor hearts that are considered acceptable, the number of heart transplants performed worldwide has declined, from a peak of about 4,070 in 1995 to fewer than 3,200 reported in each year since 2000, a 20% decrease. While some decrease in reporting from European centers may have resulted from the absence of an incentive to contribute to international registries, reported U.S. activity—which is federally mandated by organ allocation regulations—

FIGURE 37.8. Heart Transplant Survival, 1980–2006. Survival following heart transplantation in recipients, grouped by era of operation, analyzed by the Kaplan-Meier method. Operative survival accounts for much of the steady improvement in outcomes over the past two decades. The subsequent rate of attrition appears to have changed little over the past 20 years, likely reflecting the effect of competing influences such as an older recipient population and improving patient management strategies. (Figure created from data provided by the United Network for Organ Sharing, including follow-up information available as of 12/10/09.) Current demographics and statistics may be found at International Society for Heart and Lung Transplantation website (www.ishlt.org).

decreased by about 15% between 1997 and 2004 despite a steady increase in average donor age.^{15,24} A recent trend upward in U.S. heart transplant activity (from 2,000 to 2,200 cases annually) may reflect the influence of the Health Resources and Services Administration organ donor initiative,^{15,55,56} implementation in 2006 of a donor allocation algorithm that emphasizes disease acuity over proximity to donor hospital or other factors.

Operative survival in adults has improved over the past 20 years to above 90%, and both patient and graft 1-year survival rates exceed 87%^{15,16} (Fig. 37.8). The most important risk factors for death within the first year include previous transplant, increased donor age (with age older than 60 conferring greater risk than age older than 45), need for ventilator or left ventricular assist device support before transplant, and recipient age older than 60. Among common complications, rejection and infection together account for most of the mortality during the first year and contribute approximately equally (Table 37.5). Beyond the first year, malignancy, including posttransplant lymphoproliferative disease, and chronic rejection emerge as prominent additional factors limiting long-term survival. Extrapolating from current early results, more than 50% of recent recipients can expect to be alive 10 years after transplant, with actuarial graft half-life over 12 years.^{16,24,27}

Repeat heart transplantation accounts for less than 2% of all heart transplants done. When performed within the first 6 months, typically for early failure of the first graft, 1-year survival is less than 50%. When performed later, usually for cardiac allograft vasculopathy, 1-year survival is over 80%, and

TABLE 37.5**COMPLICATIONS FOLLOWING HEART TRANSPLANTATION**

Primary graft failure (<5%)
Technical (inadequate tissue preservation; reperfusion injury)
Immunologic (hyperacute rejection)
Donor selection (myocardial, valvular, or coronary obstructive disease in donor)
Technical
Size mismatch (too large, too small)
Bleeding (surgical, medical)
Anastomotic (narrowing, aneurysm, disruption)
Infection
Bacterial (various)
Viral (herpes, cytomegalovirus, Epstein-Barr virus)
Protozoal (toxoplasmosis, <i>Nocardia</i>)
Fungal (<i>Candida</i> , <i>Aspergillus</i>)
Rejection
Acute (cellular, humoral, mixed) (24%–34% within first year)
Chronic (cardiac allograft vasculopathy) (53% by 10 years)
Treatment effects
Hypertension (99% by 10 years)
Hyperlipidemia (93% by 10 years)
Diabetes (37% by 10 years)
Renal failure (acute; chronic) (39% by 10 years; 6% dialysis or transplant recipient)
Malignancy (31% by 10 years)
Skin
Visceral (lung, colon, prostate/breast, other)
Lymphoproliferative disease

has improved significantly over the past decade. Overall, actuarial graft half-life following retransplant is about 4.6 years, and is over 9 years in those who survive the first year.¹⁶ While these outcomes are significantly inferior to other transplant indications, retransplantation offers significant survival advantage for carefully selected patients.

Adolescent (11- to 17-year-olds) pediatric heart transplantation recipients fare better (>80% 1-year survival) than do younger children (1- to 10-year-olds: ~77%) or infants (younger than 1 year old: ~68%). Less favorable short-term outcomes may be ascribed to pulmonary hypertension and anatomic challenges posed by congenital heart disease, and to monitoring and compliance challenges characteristic of these age groups. Nonetheless, the graft half-life for pediatric patients (11.4 to 13 years) is similar to that for adults.^{15,16,24,27}

ETHICS

Ethical considerations are important to every aspect of heart transplantation. The donor pool is limited and appears to be shrinking despite extended donor acceptance criteria, restricting the number of patients who can undergo transplantation. This shortage forces consideration of ways to limit recipient candidacy (age limits), to increase the donor pool (presumed consent, advertising initiatives, community outreach), and to develop alternatives (mechanical devices, xenografts).^{57–59}

The heart transplant community has taken the lead in standardizing patient selection and management guidelines and has established policies for equitable organ allocation. Those given an opportunity to receive the “gift of life” are chosen from a much larger population who might benefit. Recipient candidacy decisions are made by a multidisciplinary group based on objective and subjective input from many individuals who come to know the patient and family in depth. Some recipient selection criteria are fundamentally arbitrary: age is retained as a criterion because of the limited supply of donor organs and based on the consensus view that younger patients deserve preferred access. Recipient selection criteria only become unfair if they are applied unequally or inconsistently at different programs or between various regions of the country.

Some of the most difficult decisions made by the heart transplant team involve medically marginal candidates with outstanding and effective social support or medically suitable candidates with marginal social support. While the majority of such patients will do well, outcomes in either case can, on average, be expected to fall below outcome benchmarks. For every marginal patient transplanted, a candidate who meets all the criteria may die. Thus, the “right” decision for an individual patient is difficult or impossible to know in advance and may conflict with the best interests of the population of potential recipients.

CURRENT ISSUES

Quantifiable, objective measures of efficacy beyond survival, such as improvement in exercise capacity, freedom from complications, and reduced costs, are becoming the standards by which individual heart transplantation programs are judged. Most important to the patient are subjective factors such as quality of life and productivity, for which standardized measurement tools are being developed. Meanwhile, the efficacy of any proposed alternative to transplantation must be measured against survival, cost, and quality-of-life benchmarks established by this once-experimental procedure.^{60,61}

The most important factor currently restricting the application of heart transplantation is the limited supply of donor organs. Consent is obtained from the donor’s legal representatives in only about 25% to 50% of cases where hearts are appropriate based on acceptable physiologic parameters. Various proactive approaches, such as institution of presumed consent, have been associated with high per capita donation rates in some countries. However, presumed consent is ethically dubious and may violate basic cultural or religious precepts of individuals or ethnic groups. An adverse societal response to imposition of this unpopular approach as national policy might paradoxically cripple efforts to maintain organ donation even at current levels. Well-conceived efforts to increase the rate of consent, by passing laws requiring hospitals to facilitate and document the request, by allowing trained individuals to manage the request process, and by educating the public about “the gift of life,” have boosted per capita donation in several U.S. organ procurement regions.

Efforts to develop improved immunosuppressive drugs are important and are likely to yield incremental near-term improvements in the incidence of chronic rejection. Ideally, one could induce tolerance—permanent graft acceptance without requirement for indefinite immunosuppressive therapy. Modulation, rather than suppression, of host responses to donor antigens may allow achievement of this goal.^{62,63}

Even if every physiologically suitable donor heart were available, only a minority of patients for whom transplantation would offer a survival advantage could be cared for using this modality. As technical issues related to transcatheter power delivery, thromboembolism, infection risk, and reliability are addressed, mechanical assist devices are likely to emerge as definitive “destination” therapy for some patients.⁵⁷

Progress has also been made toward use of porcine “xenografts” in man, and the initial immunologic barrier, hyperacute rejection, appears surmountable using organs from pigs genetically modified to express human complement regulatory proteins or “knocked out” for the gene encoding Gal $\alpha 1,3$ Gal, the main carbohydrate target recognized by human antipig antibodies.^{64–66} Control of subsequent cellular and antibody responses has proven difficult in animal models, but life-supporting function of renal xenografts for 3 months and heart xenografts for 1 month have been demonstrated in primates using an intensive regimen of “conventional” immunosuppressive agents.^{67,68}

Heart transplantation is one of the most resource-intensive modalities in modern medicine when assessed as cost per year of life saved. The procedure itself, the in-hospital care before transplantation, and maintenance of program infrastructure are very expensive. Ongoing pharmacy charges and surveillance procedure costs are also substantial. Paradoxically, patients physically able to return to work often cannot do so because they rely on medical disability benefits to pay for medications and follow-up care. Whether heart transplantation will continue to receive wide support is a function of societal acceptance of these costs, as currently reflected by coverage policies established by public and private health care insurers.⁶⁰ In the future the application of heart transplantation and related technologies may be limited more by what society chooses to afford, rather than what is medically possible.

CHAPTER 38 ■ PULMONARY TRANSPLANTATION

RAJA S. MAHIDHARA, JULES LIN, AND ANDREW C. CHANG

KEY POINTS

- 1 Long-term survival after lung transplant is lower in comparison to outcomes in the transplantation of other solid organs. The lack of effective medical therapy for acute and chronic rejection remains a barrier.
- 2 Candidates for pulmonary transplantation have significant functional impairment that interferes with activities of daily living. In patients with restrictive or obstructive disease, abnormal gas exchange is the major problem and essentially all require supplemental oxygen. In patients with pulmonary vascular disease, the manifestations of right ventricular failure predominate.
- 3 A paradigm shift in the allocation of donor lungs has decreased lung waitlist times and waitlist mortality. The effect of the Lung Allocation Score on short-term and long-term mortality remains to be seen.
- 4 Advances in donor management and lung preservation have been shown (a) to minimize lung injury, (b) to increase the number and quality of recoverable donor lungs, and (c) likely to be responsible for the dramatic increase in the number of lung transplants performed over the last 10 years.
- 5 It is believed that posttransplant lung injury results not only from the ischemic insult and the host immunologic response but also from reperfusion of the ischemic organ and other mediators of non-alloimmune-related injury.
- 6 Airway anastomotic healing remains a concern following transplantation but has been ameliorated by improvements in operative technique and postoperative management.
- 7 By the end of the first year after transplantation, approximately 80% of recipients report no limitations in activity.

INTRODUCTION

With nearly 18,000 lungs implanted, pulmonary transplantation comprises only 4% of the organs transplanted in the United States between 1988 and 2008. Since the first lung transplant was performed in 1963,¹ outcomes for this operation have improved dramatically, but even with advances in immunosuppression, surgical technique, and perioperative and posttransplant care, long-term survival following pulmonary transplantation remains less than that of other solid organ transplant recipients. The major problems limiting durable pulmonary transplantation have been infection, acute rejection, impaired anastomotic healing,² and chronic rejection, manifested in lung transplant recipients as the onset of bronchiolitis obliterans.³

In the lung, unlike other solid organs, systemic arterial blood supply is limited to the bronchial arteries. Because the

bronchial artery anatomy and caliber vary greatly, most transplant surgeons have not advocated reanastomosis of these vessels primarily to avoid prolonged total organ ischemia time, particularly when bilateral sequential transplantation is planned. Consequently, the bronchial anastomosis is more profoundly ischemic after transplantation and susceptible to airway dehiscence, typically within 3 weeks after transplantation. The combination of anastomotic ischemia and other factors such as infection and post-reperfusion edema hampered initial efforts to develop successful clinical programs in pulmonary transplantation.

The first combined heart and lung transplantation was performed successfully in 1981, but this procedure currently is rarely performed, with only 50 or fewer performed annually in the United States since 2000. Combined cardiac and pulmonary transplantation introduced a series of new problems related to transplanting two organs, including those associated with heart transplantation, especially accelerated coronary

artery atherosclerosis. Tracheal anastomotic healing presents less of a problem, possibly because the bronchial artery collaterals in the subcarinal space are preserved. The discrepancy between available organ donors and the increasing number of patients on the waiting list for either heart or lung transplantation as well as the observation that both short- and intermediate-term survival appears to be worse among heart–lung transplant recipients than among individuals receiving one or the other thoracic organ likely are major factors mitigating against widespread use of heart–lung transplantation.

Recognizing the potential advantage of single-lung transplantation, investigators experimentally defined the factors contributing to failure in pulmonary transplantation.⁴ They demonstrated the significant detrimental effect that corticosteroids exert on airway healing and showed that cyclosporine did not have this adverse effect. Delaying the administration of maintenance corticosteroids proved advantageous. It was later suggested that wrapping the bronchial anastomosis with a pedicle of gastrocolic omentum resulted in early capillary ingrowth and revascularization of the airway promoting healing, although this practice has not correlated with a reduction in anastomotic dehiscence.⁵

Another significant factor contributing to the improved success of single-lung transplantation was the recognition of the importance of careful recipient selection. Most early attempts at pulmonary transplantation involved severely ill, ventilator-dependent patients who had already suffered significant nutritional depletion and muscle wasting. It then became apparent that a more suitable candidate for single-lung transplantation was an individual with end-stage restrictive disease (pulmonary fibrosis), in which the allograft would receive preferential ventilation and perfusion due to increased compliance and relatively decreased pulmonary vascular resistance in the transplanted lung. Ultimately, the importance of assessing preoperative ambulatory status and of implementing intense pretransplantation pulmonary rehabilitation was recognized. Thorough patient evaluation and preparation in addition to advances in both operative techniques and immunosuppression have broadened considerably the indications for pulmonary transplantation.

As lung transplantation has become accepted more widely in the treatment of patients with end-stage lung diseases, the increasing disparity between donor organ availability and patients listed for transplantation has resulted in increasing waitlist mortality. Initial lung allocation policies were based on ABO blood type compatibility, geographic proximity to the organ donor hospital, and the amount of accumulated waiting time since listing. In 1998, the Final Rule was issued by the U.S. Department of Health and Human Services requiring increased organ sharing and development of an organ allocation system that would be more equitable and that would reduce the use of waitlist time as a criterion for allocation. In developing an allocation system, the chief priority of the Organ Procurement and Transplantation Network (OPTN) was “to reduce the number of deaths among potential and actual lung transplant candidates.”⁶ In 2005, based on analyses performed by the Lung Allocation Subcommittee of the OPTN Thoracic Organ Transplantation Committee, the Lung Allocation Score (LAS) was implemented to address the points of the Final Rule, incorporating waiting list mortality and posttransplant survival probabilities, in order to minimize waiting list mortality, increase the benefit of transplantation among recipients, and ensure equitable allocation of lungs to lung transplantation candidates.⁶ Although the impact on long-term survival remains undetermined, since implementation of the LAS (spring 2005), as indicated in the 2007 OPTN/Scientific Registry of Transplant Recipients (SRTR) Annual Report 1997–2006 (Health and Human Services [HHS]/Health Resources and Services Administration [HRSA]/Healthcare Systems Bureau [HSB]/Division of Transplantation [DOT]), there has been a dramatic reduction in the duration of median waiting list time prior to trans-

plantation, from 792 days in 2004 to 199 and 132 days in 2005 and 2006, respectively.⁷ In addition, waiting list mortality has declined from 134.6 per 1,000 patient-years in 2004 to 114.9 per 1,000 patient-years and 97.2 per 1,000 patient-years in 2005 and 2006, respectively.

INDICATIONS

- 2 Transplantation is indicated for patients with isolated organ dysfunction who have limited life expectancy despite maximal medical therapy. A patient should be referred for lung transplantation when expected survival after transplant exceeds the expected survival without transplantation. While this may seem like an obvious statement, validated data are limited with respect to the natural history of even the more common subtypes of end-stage lung disease categories including emphysema/chronic obstructive pulmonary disease (COPD), fibrotic or interstitial lung disease such as interstitial pulmonary fibrosis (IPF), or infectious lung disease, particularly cystic fibrosis. In addition, substantive changes in patient selection, operative techniques, organ preservation, immunosuppression, and other aspects of posttransplant management have led to progressively better survival after transplantation over the last 18 years.

Since the overall median survival after transplantation is approximately 5 years, the timing of transplant is an important consideration for maximizing transplant benefit. Prior to May 2005, allocation of donor lungs was based on time on the waiting list. With the large discrepancy between the number of listed transplant candidates and the limited availability of donor lungs, referral for transplant often occurred well before patients had become severely debilitated from poor respiratory function.

Lung transplantation can provide considerable palliation for dyspnea. Due to the limited availability of donors, quality-of-life improvement has been considered secondary to survival benefit, although improved outcomes in terms of factors such as oxygen dependence, physical activity, and return to work remain important in assessing the success of pulmonary transplantation.

CONTRAINDICATIONS

Table 38.1 lists absolute and relative contraindications to lung transplant. The absolute contraindications are self-explanatory and consistent with the risks associated with immunosuppression and the physical and social rigors of maintaining a complex medical regimen after transplantation of any organ. With respect to body mass index (BMI), extremes in weight have been shown to confer lower short-term survival in heart transplant patients.⁸ These findings have been reinforced by studies of lung transplantation where extremes in BMI have been shown to confer a three- to fivefold increase in 90-day mortality.^{9,10}

Overall survival for patients over the age of 65 is significantly lower than younger cohorts.¹¹ Despite this, the number of transplants in older patients has increased from less than 1% prior to 1994 to approximately 5% since 2000. Single-institution studies have demonstrated equivalent short- and intermediate-term survival in highly selected older patients.^{12,13}

Convalescence after lung transplant can be particularly grueling. Postoperative incisional pain, impaired ventilatory mechanics, malnutrition, and deconditioning impact directly on lung function as with any pulmonary operation. In the earlier eras of lung transplantation, ventilator-dependent, malnourished patients or those with immune suppression–related myopathy and osteoporosis experienced very poor survival. Recipients had marked improvement in survival in the late 1980s and early 1990s due to the recognized value of preoperative pulmonary rehabilitation and improved selection of

TABLE 38.1 INDICATIONS/CONTRAINDICATIONS**CONTRAINDICATIONS TO LUNG TRANSPLANTATION****ABSOLUTE CONTRAINDICATIONS**

Recent malignancy other than nonmelanoma skin cancer
 End-stage extrapulmonary organ dysfunction (i.e., cirrhosis, dialysis-dependent renal insufficiency)
 Active sepsis
 Active HIV infection
 Active hepatitis B or C infection with histologic evidence of liver damage
 Current or recent tobacco use
 History of alcohol or drug abuse/addiction
 Severe psychiatric illness
 History of noncompliance with medical therapies
 Malnutrition (BMI <18)

RELATIVE CONTRAINDICATIONS

Age >65
 Debilitation (6-minute hall walk <150 meters)
 Mechanical ventilation
 Extrapulmonary organ dysfunction
 Coronary artery disease
 Gastroesophageal reflux disease
 Osteoporosis
 Poorly controlled chronic medical conditions (e.g., diabetes, hypertension)
 Chronic high-dose steroid dependence
 Chest or spinal deformity
 Obesity (BMI >32)
 Severe pleural disease including empyema, fungal infection, and pleurodesis
 Chronic infection with HIV or hepatitis B or C

BMI, body mass index; HIV, human immunodeficiency virus.

ambulatory patients. Pulmonary transplantation still may be suitable in highly selected nonambulatory or ventilator-dependent patients as demonstrated in small single-center series¹⁴ including patients who have had rapid deterioration in lung function and who have had only brief periods of debilitation. Although patients with end-stage extrapulmonary organ dysfunction are not candidates for lung transplant, limited experience has demonstrated acceptable survival in patients with surgically or percutaneously correctable coronary artery disease.¹⁵

Disease-Specific Indications

Disease-specific indications for lung transplantation are listed in Table 38.2.

Chronic Obstructive Pulmonary Disease. COPD is the most common indication for lung transplantation, accounting for 51% of single-lung and 37% of bilateral lung transplants since 1995.¹¹ Advances in the medical therapy of patients with emphysema that can prolong survival include smoking cessation, long-acting bronchodilators, oxygen supplementation, optimization of nutrition, pulmonary rehabilitation, and vaccination for pneumonia and influenza. In addition, lung volume reduction surgery has been shown to confer survival ben-

TABLE 38.2 INDICATIONS/CONTRAINDICATIONS**DISEASE-SPECIFIC CONSIDERATIONS FOR LUNG TRANSPLANTATION****COPD**

BODE index >7 or hospitalization for exacerbation with hypercapnia ($\text{PCO}_2 > 50$ mm Hg)
 Pulmonary hypertension
 $\text{FEV}_1 < 20\%$ and either $\text{DLCO} < 20\%$ or non-upper-lobe-predominant emphysema

IPF

Histologic or radiographic evidence of UIP and $\text{DLCO} < 39\%$
 >10% decrease in FVC on 6-month follow-up
 $\text{SaO}_2 < 88\%$ during a 6-min walk test
 “Honeycombing” on HRCT (fibrosis score ≥ 2)

CF

$\text{FEV}_1 < 30\%$ or rapid decline in FEV_1 on follow-up
 Exacerbation requiring ICU stay
 Increasing frequency of exacerbations
 Refractory or recurrent pneumothorax
 Increasing oxygen requirements
 Hypercapnia
 Pulmonary hypertension

PAH

NYHA class III or IV on maximal therapy
 Low or declining 6-min walk test
 Cardiac index <2.0
 Right atrial pressure >15

BODE, body mass, airflow obstruction, degree of dyspnea, and exercise tolerance; CF, cystic fibrosis; DLCO, carbon monoxide diffusing capacity; FEV_1 , forced expiratory volume in 1 second; HRCT, high-resolution computed tomography; IPF, interstitial pulmonary fibrosis; NYHA, New York Heart Association; PAH, pulmonary artery hypertension; UIP, usual interstitial pneumonia.

Taken from Orens JB, Estenne M, Arcasoy S, et al. International guidelines for the selection of lung transplant candidates: 2006 update—a consensus report from the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant* 2006;25(7):745–755.

efit in patients with upper lobe–predominant disease, impaired exercise capacity, and the absence of high-risk factors including forced expiratory volume in 1 second (FEV_1) less than 20% or carbon monoxide diffusing capacity (DLCO) less than 20%.¹⁶ Referral for transplantation should occur for patients who deteriorate despite maximal therapy and who are not candidates for lung volume reduction.

Factors associated with poor survival in patients with COPD include respiratory exacerbation with hypercapnia, hypoxia, pulmonary hypertension, increasing age, decreasing FEV_1 , decreasing DLCO, and increased BMI.¹⁷ A prospectively validated index based on body mass, airflow obstruction, degree of dyspnea, and exercise tolerance (BODE) has been proposed as a robust predictor of mortality in patients with COPD. A BODE index of greater than 7 on a scale from 0 to 10 was associated with a median survival of 3 years.¹⁸

Idiopathic Pulmonary Fibrosis. Usual interstitial pneumonia (UIP) is the pathologic correlate of IPF and is the most common subtype of interstitial pneumonia. Pulmonary fibrosis

has been the second most common indication for lung transplantation, accounting for 28% of single-lung transplants and 14% of bilateral lung transplants since 1995.¹¹ In 2006, IPF accounted for 32% of all lung transplants performed.

Although the options for effective medical therapy of patients with IPF are limited and patient mortality is high with median survival of 3 to 4 years following diagnosis, patients experience a varying clinical course, with some patients progressing rapidly and others following a more indolent deterioration. Risk factors for poor survival include a pathologic diagnosis of UIP (vs. other type of interstitial pneumonia), severe fibrosis by high-resolution computed tomography, the presence and severity of pulmonary hypertension, and acute pulmonary exacerbations.

Assessment of pulmonary function and exercise capacity also can be used to identify subgroups of patients with pulmonary fibrosis at higher risk for mortality. A baseline DLCO of less than 39% and greater than 10% decrement of DLCO or forced vital capacity (FVC) over a 6- to 12-month period are associated with an increased risk of death.^{19,20} Oxygen desaturation and shorter walk distance during 6-minute walk testing independently predicted increased mortality in patients diagnosed with pulmonary fibrosis.²¹

Cystic Fibrosis/Bronchiectasis/Infection-related End-stage Lung Disease. Cystic fibrosis (CF) is the third most common indication for lung transplantation, accounting for 20% of lung transplants performed in 2006, with most recipients undergoing bilateral transplantation.¹¹ Colonization of the airway with resistant organisms is common in these patients and is not an absolute contraindication to transplantation, although overt sepsis is an absolute contraindication to transplantation. Single-institution studies have identified colonization with *Burkholderia cepacia* genomovar III (redesignated as *Burkholderia cenocepacia*) to be associated with a 30% to 40% increase in posttransplant mortality, although this finding has not been validated in a multi-institutional setting.

Among patients with pulmonary disease due to cystic fibrosis, the time course of respiratory deterioration is highly variable. As a consequence, the criteria for pulmonary transplantation in this population have been difficult to define by risk modeling, although deterioration of FEV₁ to below 30% of predicted remains an indication for referral to evaluation, although not for immediate listing.^{22,23} Other factors to consider include increasing oxygen requirement, hypercapnia, and pulmonary hypertension.²⁴

Pulmonary Artery Hypertension. Idiopathic pulmonary artery hypertension (PAH) has a median survival of less than 3 years if untreated. Although a more common indication for transplantation in the past, effective medical therapies including vasodilator therapy and continuous intravenous epoprostenol have prolonged survival in this population. Patients with a history of right heart failure or poor pretreatment functional status and those who, despite vasodilator therapy, have demonstrated either no response or functional deterioration should be referred for pulmonary transplantation. Modern guidelines emphasize progressive deterioration of right heart function despite maximal medical therapy as an appropriate indication for referral.²⁴ Patients with left ventricular heart failure requiring inotropic support may not be suitable candidates for pulmonary transplantation alone but instead should be considered for en bloc heart-lung transplantation.

in the process of donor allocation. Prior to 2005, recipients were prioritized by length of time spent on the waiting list as well as other factors including size, ABO compatibility, and geographic location. In compliance with the Final Rule mandate of 1998 to allocate organs based on urgency (risk of dying without a transplant) and utility (minimizing transplantation of patients with low transplant survival), the Lung Allocation Score was developed by the Thoracic Committee of the OPTN.

Prior existing data to determine transplant benefit were conflicting. An analysis of all transplant patients with COPD, IPF, and CF from 1992 to 1994 demonstrated a survival benefit for patients with IPF and CF but not with COPD.²⁵ A similarly powered analysis of the European transplant experience demonstrated survival benefit for all lung transplant groups.²⁶ Recent studies also had called into question the transplant benefit for children with cystic fibrosis listed between 1992 and 2002 for pulmonary transplantation.²⁷ In this latter study, evaluating patients listed before implementation of the new LAS system, over half of the patients had a predicted median survival of greater than 5 years at the time of operation.

Egan et al. for the SRTR⁶ analyzed over 4,000 patients on the UNOS lung transplant waiting list in order to identify markers of waitlist mortality. The listing diagnoses for these patients—COPD, IPF, CF, and PAH—accounted for 80% of the transplants performed at the time. Striking differences in waitlist mortality were noted, with patients listed for emphysematous diseases experiencing a 1-year waitlist mortality of less than 14% compared with 1-year waitlist mortality between 28% and 33% among patients listed with the other three primary diagnoses. Transplant candidate demographics, hemodynamic parameters, measures of pulmonary function, and other clinical variables were used to create a regression model. Similarly, a predictive model for posttransplant survival was developed. When these models were applied to evaluate survival in 2,484 patients with the aforementioned four primary diagnoses, factors including increasing recipient age, intensive care unit (ICU) admission, and need for mechanical ventilation were significant predictors for 1-year survival. Variables included in the LAS calculator are listed in Table 38.3. The normalized

LUNG ALLOCATION AND TRANSPLANT BENEFIT

- 3** Perhaps the most significant change in the practice of lung transplantation over the last 10 years has been a paradigm shift

lung allocation score ranges from 0 (lowest priority) to 100 (highest priority) with the intent of balancing urgency (waitlist mortality) and benefit (posttransplantation survival).

The LAS has been implemented for over 4 years and has had a clear impact on outcomes in lung transplantation. The number of active waitlist patients has declined by 54% as early listing confers no advantage. Waiting time to transplantation has decreased from 792 days in 2004 to 141 days in 2007. Death rates on the waiting list have been consistently declining over the past decade and have continued to decrease since implementation of the LAS. The death rate did not, however, decline as much as might be expected, possibly as a consequence of an overall increase in the acuity of the waiting list.

Overall early survival (30-day and 1-year) has enjoyed a slow but steady improvement since 1995, which has carried through the implementation of the LAS in 2005. The impact of the LAS on intermediate- and long-term outcomes is not yet evaluable. An increasing LAS score, however, is associated with lower 1-year survival. Transplanted patients with an LAS score less than 35 had a 1-year survival of 85.7%, whereas those with an LAS score greater than 60 had a 1-year survival of 71.3%.²⁸ The impact of the LAS on maximizing transplant benefit is not clear at this time. Reevaluation and revision of the criteria that determine the LAS remains one of the objectives of the Thoracic Organ Transplantation Committee of the OPTN.

DONOR CONSIDERATIONS

Donor Selection

The shortage of acceptable donors for lung transplantation is highlighted by the observation that although the number of lung transplants has steadily increased (1,465 in 2007) and waitlist times and waitlist death rates have decreased, the total number of registrants on the wait list has remained the same.²⁸ The reasons that fewer lungs are offered or accepted compared to other organs is manifold. Death from head injury or bleeding may lead to neurogenic pulmonary edema, while chest trauma can result in contusion or pneumothorax. All brain-dead donors are intubated and at risk for aspiration and nosocomial pneumonia, especially if there is a prolonged interval between hospitalization and declaration of brain death. Finally, hemodynamic instability, whether from herniation or trauma, often results in significant volume resuscitation that can contribute to acute lung injury.

Bronchoscopy allows for direct examination of the bronchial tree and for microbiologic examination of bronchial secretions, the results of which may influence later treatment of the recipient. Chest radiography and computed tomography are useful to evaluate for effusions or pulmonary infiltrates, consolidation, and contusion that might be contributing to donor hypoxemia. Unlike other solid organ transplants, lungs are unique in carrying a relatively high risk of intrinsic infection (i.e., pneumonia) following transplant. Infiltrates typically preclude donor candidacy. A small infiltrate in one lung without evidence of purulent secretions may still allow this lung to be used in conjunction with a contralateral normal lung in a bilateral lung transplant. Moreover, a pulmonary infiltrate does not necessarily preclude use of the contralateral lung for single-lung transplant.²⁹ Not infrequently, the lungs of a particular donor may not be suitable because of infiltrates when all other organs are acceptable. Because all brain-dead patients have endotracheal tubes and are on mechanical ventilation, there is a high likelihood that the airway is either colonized with bacteria or that there is ongoing invasive pulmonary infection. With pulmonary infection, an infiltrate often is present on the screening chest radiograph.

Aspiration at the time of the insult that resulted in brain death is a common cause of pulmonary infiltrates in potential

donors. Signs of aspiration may not be evident on a chest radiograph for 24 to 48 hours, underscoring the importance of the bronchoscopic examination when evaluating donor candidacy. Characteristic early bronchoscopic evidence of aspiration includes erythematous tracheobronchial mucosa, purulent secretions, and occasionally the presence of food particles.

Major pulmonary contusion resulting from blunt chest trauma also may eliminate lungs from donor consideration, but minor to moderate contusions unilaterally are often acceptable. Evaluating the full extent of contusion at the time of donor retrieval can be difficult because the interval from injury to determination of brain death and donation may be short. Although the detrimental effect on gas exchange caused by a pulmonary contusion is usually transient, further bleeding into the lung parenchyma could occur if cardiopulmonary bypass is required to perform the transplantation. Pulmonary edema may occur as a result of massive head injury and may be exacerbated by donor management protocols directed at maintaining satisfactory nonpulmonary organ perfusion and function.

The well-recognized limitation of donor organ availability is compounded by the relatively fewer usable lungs per donor. Criteria for an acceptable donor lung are particularly stringent, as listed in Table 38.4.³⁰ This consensus statement highlights the dearth of data available to validate these criteria. Multiple single-institution retrospective reports looking at “extended criteria” donors (those who do not meet one or more ideal criterion) have been published with conflicting results on nearly every single criterion with respect to postoperative, short, and long-term outcomes. Clinically, these selection criteria provide an overall gestalt of the quality of the donor. If one aspect of the donor is marginal, the donor lungs can still be acceptable; however, when multiple criteria are not met, the risk of transplanting such lungs might be increased. There are several caveats that have come into “standard” practice. Although leukocytes or occasional bacteria on sputum Gram stain can be acceptable, the presence of gross pus or fungal elements confers a high risk of perioperative complications.³¹ In the annual report of lung transplant outcomes, increasing donor age modestly increased the risk of 5-year mortality.¹¹ Analysis of a large cohort of more than 750 lung and heart–lung recipients demonstrated significantly worse long-term survival with ischemic times greater than 330 minutes. Hazard ratios for death were threefold higher in patients with ischemic times of 8 hours and nearly eightfold higher when ischemia reached 10 hours.³² The detrimental effects of older donor age and longer ischemic times appear to be additive.³³

TABLE 38.4

MANAGEMENT

CRITERIA FOR IDEAL LUNG DONORS

Age <55y
ABO compatibility
Height match within 20% of recipient
Clear chest radiograph
PaO ₂ >300 on FiO ₂ of 1.0, PEEP 5 cm H ₂ O
Tobacco history of <20 y
Absence of chest trauma
No evidence of aspiration or pulmonary sepsis
No previous cardiothoracic surgery
Negative sputum Gram stain
Absence of purulent secretions

PEEP, positive end-expiratory pressure.

ALGORITHM 38.1. University of Michigan donor management algorithm.

Donor Management

- 4 Despite the inability to identify “extended” donor criteria that reliably provide acceptable grafts, donor management optimization has allowed an increase in donor recovery and is likely responsible for the increase in the overall number of transplants performed over the last decade. Algorithm 38.1 outlines the donor management algorithm used at the University of Michigan. Key principles include the early use of steroids and thyroxine to prevent neurogenic pulmonary edema and to maintain cardiovascular stability, alveolar recruitment with high positive end-expiratory pressure (PEEP) and aggressive endotracheal lavage for patients with partial pressure of arterial oxygen (PaO₂) less than 300 mm Hg, optimization of intravascular volume, maneuvers to prevent aspiration, and lung-protective ventilation utilizing high frequency, low tidal volumes, and high PEEP to prevent volutrauma and barotrauma to the lungs. These maneuvers have been shown to double the organ recovery rate without detrimental effects on 30-day or 1-year survival.³⁴ The presence of a dense infiltrate or purulent secretions in one lung does not preclude the use of the contralateral lung for single-lung transplant.

Investigators at the Texas Organ Sharing Alliance identified 330 potential lung donors over a 4-year period preceding initiation of an active donor management protocol and 381 potential donors managed on the protocol in the subsequent 4 years.³⁴

Overall, 1.7 organs per donor were procured in 19% (136/711) of potential donors. Prior to initiation of the management protocol, organ procurement occurred in only 12% (38/330), recovering 1.6 lungs per donor. In contrast, with lung-protective donor management, organ procurement occurred in 26% (98/381), recovering 1.7 organs per donor.

Following initial organ acceptance, the lungs are declined when the procurement team identifies significant purulent secretions during bronchoscopy or when arterial blood gases deteriorate significantly between the time of acceptance and when the procuring team reassesses the donor upon arrival at the donor hospital. On-site measurement of pulmonary vein blood gases at the time of donor sternotomy can aid the procuring team in determining whether donor hypoxemia is due to unilateral or bilateral organ compromise.³⁵ Size of the donor lungs is less important when the recipient suffers from emphysema, in which each hemithorax is very large, compared with pulmonary fibrosis, in which the hemithorax can be significantly contracted. The most important size consideration is a reasonable match between donor and recipient height.

Lung Preservation

Unlike the kidney, liver, or pancreas, immediate acceptable function of the transplanted lung is vital for survival of the recipient. Primary graft dysfunction occurs in 10% to 25% of

cases, is the most common cause of 30-day mortality after lung transplantation, is associated with higher rates of chronic rejection (bronchiolitis obliterans syndrome), and correlates with increased 1-year and 5-year mortality.³⁶

Ischemia-reperfusion injury refers to the cellular and architectural changes that occur from donor aortic cross-clamp to release of the recipient pulmonary artery clamp (ischemic phase) through the immediate restitution of systemic gas exchange (reperfusion phase). Minimizing ischemia-reperfusion injury is crucial in ensuring good early graft function. Advances in donor lung preservation techniques have led to more consistent quality of the donor allograft and lower rates of primary graft dysfunction.

A major development in lung preservation over the last 5 years has been the widespread clinical use of a preservation solution specifically designed for the lung. Traditional preservation solutions such as Euro-Collins were designed to maintain intracellular ion balance and cell-wall integrity. Low-potassium dextran (Perfadex, Vitrolife, Goteborg, Sweden) has an extracellular fluid ion balance and has been shown to have beneficial effects on endothelial cell function and pulmonary microcirculation. Five single-institution reports have demonstrated significantly better initial lung function with low-potassium dextran, while one study showed no difference.³⁷

The donor allograft is cooled to minimize cellular metabolism while maintaining vital cellular function. Although small animal studies have demonstrated better postischemic function at preservation temperatures between 15°C and 23°C, practical constraints have led to the common practice of cooling to 4°C to 8°C (the temperature of ice water). Other techniques that have traditionally been employed to ensure rapid homogeneous cooling of the lung include topical cooling, antegrade flush through the pulmonary artery, and techniques to maintain patency of the microcirculation including the administration of prostaglandins prior to cross-clamp and maintenance of ventilation after cross-clamp. Retrograde flush through the pulmonary veins purges the pulmonary and bronchial circulations, has more homogeneous distribution, and can evacuate clot or fat emboli. Clinically, retrograde flushing has been shown to improve immediate posttransplant oxygenation in combination with antegrade flush.³⁸

Optimizing storage technique has also evolved. After flushing of the pulmonary circulation, the lungs are recruited to expand atelectatic areas and the trachea is stapled and divided prior to separation from the donor and storage for transport. Methods of lung recruitment have been studied in animal models and have shown that ventilation with less than 50% oxygen and maintenance of airway pressure between 15 and 20 cm H₂O have beneficial effects on capillary leak, lipid peroxidation, and barotrauma.³⁹⁻⁴¹

5 It is believed that lung injury results not only from the ischemic insult but also from reperfusion of the ischemic organ. Several experimental models of acute lung injury implicate oxygen free radicals as a factor in the genesis of reperfusion

injury. A significant early increase in lung permeability is seen after an ischemic period followed by reperfusion, which improves within several hours. Changes in the contralateral, nonischemic lung are presumably the result of substances released during reperfusion of the ischemic lung. Animal models have demonstrated that gradual pressure-controlled reintroduction of blood flow and a protective ventilation strategy of high frequency and low tidal volume reduces lung injury.^{42,43}

TRANSPLANTATION OPERATION

The decision to proceed with single-lung or bilateral lung transplantation depends on several factors, including the etiology of respiratory insufficiency and donor lung availability. Patients with chronic infection, such as those with cystic fibrosis or immunoglobulin deficiency disorders, require replacement of both lungs. Single-lung transplantation can be considered for patients with restrictive physiology (pulmonary fibrosis), particularly if there is no evidence of secondary pulmonary hypertension. In patients with end-stage obstructive lung disease, specifically emphysema, early in the pulmonary transplantation experience, it became evident that single-lung transplantation was associated with altered physiology arising from hyperventilation of an overly compliant native emphysematous lung left in situ. Air trapping in the overly compliant native lung, combined with the resultant mediastinal shift, resulted in a significant ventilation and perfusion mismatch, as well as poor expansion and compromised function of the transplanted lung. Despite such concerns, it also has been demonstrated that single-lung transplantation not only is an acceptable operation for patients with emphysema but also may be the operation of choice for patients older than 50 years.⁴⁴ In contrast, bilateral lung transplant recipients appear to have greater improvement of FEV₁ and 6-minute walk testing when compared with single-lung transplant recipients, at 1-year follow-up.⁴⁵

Bilateral lung transplantation, when indicated, has been simplified by the development and refinement of the sequential lung transplant procedure rather than en bloc double-lung operation, which required a tracheal anastomosis with cardiopulmonary bypass and resulted in significant perioperative cardiac morbidity and mortality.⁴⁶ Bilateral sequential lung transplant can be approached either by median sternotomy or bilateral thoracotomies and with or without cardiopulmonary bypass depending on the indication for transplantation. A bilateral thoracosternotomy incision ("clamshell") permits easier completion of the recipient pneumonectomies than median sternotomy, but the clamshell incision tends to be more painful. A candidate's past history of chest operations does not alone preclude eligibility for bilateral lung transplantation.

In patients with pulmonary hypertension, single-lung transplantation historically had been felt to be adequate to unload the right ventricle, reduce pulmonary artery pressure, and thus lead to improved right ventricular function (Table 38.5). Currently,

TABLE 38.5

COMPLICATIONS

TYPICAL HEMODYNAMICS DATA FOR SINGLE-LUNG TRANSPLANTATION IN PATIENTS WITH PULMONARY HYPERTENSION

■ MEASUREMENT	■ PRETRANSPLANT	■ POSTTRANSPLANT
Pulmonary artery pressure		
Mean	58 mm Hg	16 mm Hg
Systolic	94 mm Hg	28 mm Hg
Right ventricular ejection fraction	25%	52%
Cardiac output	4 L/min	7 L/min
Pulmonary vascular resistance	1,302 dyne/cm ⁵ /s	161 dyne/cm ⁵ /s

although no significant survival benefit is demonstrable between patients treated with single-lung, bilateral lung, or heart–lung transplantation, most patients receive predominantly bilateral sequential transplantation, unless there is evidence for inotrope-dependent heart failure.⁴⁷ Patients with pulmonary arterial hypertension listed for lung transplantation tend to be younger, and thus may be more likely to obtain more durable improvement in lung function following bilateral lung transplantation. In addition, perioperative management and improved hemodynamic performance appear to be facilitated by bilateral rather than single-lung transplantation. Although seemingly contradictory, bilateral lung transplantation for this population also might improve organ utilization, since marginal lungs likely are more readily available than a single “ideal” donor lung.

OPERATIVE TECHNIQUE

Single-lung Transplantation

The performance of the donor operation does not vary because one always attempts to use both lungs, either for single-lung replacement on two recipients or for distribution in another transplant medical center. This practice provides the most efficient use of limited donor organs. In the recipient operation, a standard fourth intercostal space posterolateral thoracotomy is performed. In patients with emphysematous disease, muscle-sparing axillary thoracotomy can be performed, but this approach might not afford suitable exposure for patients who have significant volume loss due to severe pulmonary fibrosis, previous thoracotomy, or pleurodesis. The hilar dissection (Fig. 38.1) differs from that of a pneumonectomy in that the main pulmonary artery should be mobilized and divided distal to the origin of the first segmental trunk and the pulmonary veins should be divided at the main segmental tributaries as they return to the superior or inferior veins. Care should be taken to preserve lymphatic and areolar tissue at the point of division of the mainstem bronchus in order to maintain its vascular supply. When the donor lung arrives in the operating room, the recipient pneumonectomy is performed by dividing the hilar vessels as far *distally* as possible and the bronchus at the level of the upper lobe take-off.

The implantation procedure begins with construction of an anastomosis between the donor and recipient bronchus. End-to-end anastomosis, with running suture approximation of the

membranous airway and figure-of-eight suture approximation of the cartilaginous airway using monofilament absorbable suture, appears to reduce bronchial anastomotic complications and permits adjustment for potential donor–recipient size mismatch, particularly when completing the cartilaginous portion.^{48,49} The peribronchial areolar and lymphatic tissue can be reapproximated between the donor and recipient, particularly anteriorly, in order to separate the bronchial and pulmonary arterial anastomoses. Advocates of bronchial arterial bypass with a native internal mammary have demonstrated decreased bronchial anastomotic complications in small series, but this technique has not received widespread acceptance.^{50–52}

The vascular anastomoses are then performed sequentially using running nonabsorbable monofilament sutures. Our preference has been to first perform the pulmonary arterial anastomosis and then the left atrial anastomosis. The recipient left atrial cuff is typically prepared by cross-clamp of the left atrium and unifocalization of the branch pulmonary veins. Once the vascular anastomoses are constructed, clamps are removed and blood flow is reestablished as the lung is inflated, with care taken to de-air the left atrial anastomosis prior to securing the anastomotic suture line. The chest is closed in standard fashion. Either the right or left lung can be transplanted, and the decision of which side to transplant is based on both donor lung availability and recipient quantitative perfusion lung scan data. If one lung receives most of the perfusion, the opposite lung typically is transplanted.

Bilateral Lung Transplantation

The technique of double-lung transplantation has evolved considerably since the late 1980s from en bloc replacement to bilateral, sequential lung replacement.^{46,53} With the patient in the supine position, this operation can be performed through sternotomy, bilateral thoracosternotomy (clamshell) incision (Fig. 38.2), bilateral anterior thoracotomies without sternal division, or bilateral muscle-sparing axillary thoracotomies. The bilateral thoracosternotomy incision provides the broadest exposure to the hemithoraces, facilitating dissection and mobilization of hilar structures. This exposure is particularly important in recipients with diffuse dense adhesions between the visceral and parietal pleural surfaces, as is often seen in patients with chronic infection and bronchiectasis, such as those with cystic fibrosis.

FIGURE 38.1. Mobilization of the hilum of the right lung demonstrating the encircled pulmonary artery with the first branch ligated and divided. The superior and inferior pulmonary veins have been exposed. Both the artery and veins are taken as close to the lung as possible. The bronchus is divided at the level of the take-off of the upper lobe.

FIGURE 38.2. Patient positioning for bilateral, sequential pulmonary transplantation operation. The chest incision, a bilateral thoracosternotomy, is seen, as is the separate midline incision used to expose the omentum (if necessary). The sternum is divided transversely, and the fourth intercostal space on each side is entered.

Although both lungs are replaced, the operation often can be performed without cardiopulmonary bypass unless the recipient has significant pulmonary hypertension or severely limiting DLCO. By replacing the lung with the least function first, patient oxygenation and ventilation are maintained by the native lung that receives the major fraction of perfusion. If the patient is unable to tolerate single-lung ventilation due to either inadequate gas exchange or worsening right ventricular dysfunction and worsening pulmonary hypertension (near- or suprasystemic), then cardiopulmonary bypass is instituted. If recipient hemodynamics are impaired significantly during retraction and exposure of the left atrial anastomosis, particularly during left lung recipient pneumonectomy and implantation, opening the recipient pericardium can be sufficient to permit safe manual cardiac retraction or application of an apical cardiac stabilizer.⁵⁴ Initiation of cardiopulmonary bypass will also provide sufficient cardiac decompression in order to obtain adequate and safe exposure to complete the remaining anastomoses.

The donor lungs are separated as for single-lung transplantation, leaving a cuff of left atrium around the pulmonary veins on each side. The recipient pneumonectomy is carried out with the patient maintained on one-lung ventilation. Each donor lung is implanted using essentially the same technique as described for single-lung transplantation. The bronchial anastomosis is completed first, followed by the vascular anastomoses. Once perfusion and ventilation are restored to the first implanted lung, this lung then supports the patient while the remaining lung is removed and the second lung is implanted.

RESULTS

The Registry of the International Society of Heart and Lung Transplantation (ISHLT) has recorded 24,904 lung transplants between 1985 and 2006.¹¹ Currently, 147 centers actively perform lung transplants, but only 23 centers perform more than 30 per year. Of the 2,168 lung transplants performed captured by the ISHLT in 2006, over 67% of patients transplanted received bilateral lung transplants. The single most common indication for transplant was emphysema either as a result of α_1 -antitrypsin deficiency (4% of cases) or idiopathy (32% of cases). Most of the so-called idiopathic cases of emphysema are related to cigarette smoking. Pulmonary fibrosis, the indication first treated successfully by lung transplantation, accounted for 26%, while cystic fibrosis accounted for 16%.

Overall, survival after transplant has steadily improved with time. In the era between 1988 and 1994, median survival was 3.9 years, while survival from 2000 to 2006 has increased to 5.5 years. In this most recent epoch of lung transplant, the overall 1-year survival rate following lung transplant is 81.4% and the 5-year survival is 53.5%. Patients receiving bilateral lung transplant survive significantly longer than patients after single-lung transplant (median survival of 6.2 vs. 4.5; $p < 0.0001$). In general, younger recipients enjoy longer survival than older patients. Patients with cystic fibrosis have the best median survival (6.4 years) as they comprise a younger population and in general will receive two lungs secondary to infectious lung disease. Median survival for patients with pulmonary fibrosis is significantly lower at 4.1 years, and that of patients with COPD is 5 years.

For all recipients, the factors associated with the highest risk of 1-year mortality were the era in which patients were transplanted, intravenous inotropes, and mechanical ventilation. The most significant risk factor, by far, for 5-year mortality was development of bronchiolitis obliterans syndrome within the first year of transplant.¹¹ Outcomes in lung transplant have clearly improved over time. The impact of changes in lung allocation in the United States on early and late outcomes remains to be seen.

IMMUNOSUPPRESSION

Immunosuppression is initiated in the immediate perioperative period and continued for the rest of the recipient's life. UNOS registry data show that regimens typically include a calcineurin inhibitor, either cyclosporine or tacrolimus; a purine synthesis antagonist, either azathioprine or mycophenolate mofetil; and a corticosteroid, either methylprednisolone (intravenous) or prednisone (oral). In a recent open-label randomized trial of 90 patients who received either cyclosporine or tacrolimus,⁵⁵ subjects who were treated with tacrolimus experienced significantly less acute rejection. Lymphocytic bronchitis was less frequent among patients receiving tacrolimus. In addition, fewer (but not statistically significant) patients developed stage 0-p bronchiolitis obliterans syndrome. These investigators used a composite endpoint including cumulative acute rejection score, cumulative lymphocytic bronchitis score, or the development of bronchiolitis obliterans syndrome stage 0-p (10% or greater decrease in FEV₁). No difference in graft survival was noted. Although diabetes was slightly more prevalent among subjects treated with tacrolimus, there were no differences observed between the two treatment groups in terms of hypertension, chronic renal disease, posttransplant malignancy, or total number of infections.

In other solid organs, use of induction (perioperative) antithymocyte regimens appears to be salutary in reducing both acute and chronic rejection. There are limited data supporting the use of such agents in lung transplantation. In a study of 44 patients randomized to conventional triple-drug immunosuppression

with or without rabbit antithymocyte globulin, a significant reduction in early acute rejection from 41% to 5% was observed with the use of rabbit antithymocyte globulin, but there was no apparent effect on the total number of rejection episodes. Time to onset of bronchiolitis obliterans syndrome was earlier, and graft survival worse, with conventional treatment only, but these differences were not statistically significant. Several studies comparing antithymocyte globulin with T-cell-specific interleukin-2 (IL-2) receptor (CD25) monoclonal antibody suggest that outcomes, including early acute rejection and freedom from rejection, are equivalent⁵⁶ if not worse^{57,58} for patients treated with IL-2-receptor antibody. Treatment-related complications, particularly cytomegalovirus infection, appear to be equivalent for these induction agents. These studies do not provide sufficient evidence, and likely lack sufficient power, to determine whether their use is beneficial for the prevention of acute or chronic rejection. Two important issues regarding standard immunosuppressive therapy are the myriad side effects associated with these agents and their numerous interactions with other commonly prescribed medications.⁵⁹

Rapamycin (sirolimus) is a serine/threonine kinase inhibitor that can be used as a second-line agent for treatment of acute rejection, sometimes in combination with calcineurin inhibitors, but such use is considered off-label and not recommended. In addition, rapamycin is contraindicated absolutely in the early posttransplantation period because of its association with fatal bronchial anastomotic dehiscence.

COMPLICATIONS

Complications resulting from pulmonary transplantation occur frequently, may be severe, and occasionally result in death. Intraoperative complications include technical problems with the vascular or bronchial anastomoses, injury to the phrenic or recurrent laryngeal nerves, and myocardial infarction. Early postoperative complications include primary graft dysfunction, infection, and problems with airway healing and acute rejection. The most common late complications are infection and bronchiolitis obliterans (chronic rejection). Intra-abdominal complications are not uncommon. Wound infection is noted rarely. Noninfectious, nonpulmonary complications related to immunosuppression are common. The cumulative prevalence within 5 years after transplant of hypertension, renal insufficiency, hyperlipidemia, and diabetes is 85.3%, 37.0%, 53.6%, and 35.5%, respectively.¹¹ Finally, there is a three- to fourfold higher risk of malignancy in patients after transplant.⁶⁰

Causes of recipient death can be categorized according to the time frame in which they occur. Early deaths (sooner than 30 days following transplant) most commonly result from primary graft failure (28.2%).¹¹ Infection is the second most common cause of early death (20.3%), followed by heart failure (11.1%). Rejection accounts for 4.3% of deaths in the early posttransplantation period. Hemorrhage and airway dehiscence each are responsible for 8.3% of early postoperative deaths. Infection accounts for about 39.5% of deaths within the first year of transplant (after 90 days). About one third of deaths result from manifestations of chronic rejection and obliterative bronchiolitis, the single biggest impediment to long-term survival following lung transplantation. Respiratory failure and malignancy are the next most common causes of late mortality. Despite the major strides made in the operation itself and early postoperative care, the complications resulting from chronic immunosuppression continue to plague transplant patients.

Primary Graft Dysfunction

Mild, transient pulmonary edema is a common feature of the freshly transplanted allograft. In approximately 15% of cases, the injury is sufficiently severe to cause a form of acute respira-

TABLE 38.6 **STAGING**

GRADING OF PRIMARY GRAFT DYSFUNCTION SEVERITY

■ GRADE	■ PaO ₂ / FiO ₂	■ RADIOGRAPHIC INFILTRATE CONSISTENT WITH PULMONARY EDEMA
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

tory distress syndrome termed *primary graft failure*. Primary graft failure is presumed to reflect ischemia-reperfusion injury, but surgical trauma and lymphatic disruption may be contributing factors. The diagnosis rests on the presence of widespread infiltrates on chest radiographs, severe hypoxemia within 72 hours after transplantation, and the exclusion of other causes of graft dysfunction, such as volume overload, pneumonia, rejection, occlusion of the venous anastomosis, and aspiration. Treatment is supportive, relying principally on conventional mechanical ventilation. Independent lung ventilation, inhaled nitric oxide, and extracorporeal membrane oxygenation have been used as adjunctive measures. Mortality rates of up to 60% have been reported, and among those who survive, the recovery period is often protracted, but achievement of normal allograft function is possible. The results of emergency retransplantation in such cases have been poor.^{59,61,62}

The impact of primary graft dysfunction on outcomes has been muddled by variability in the definition of this syndrome historically. A consensus statement by the ISHLT in 2005 sought to standardize the definition and severity of primary graft dysfunction (Table 38.6).⁶³ Studies examining outcome utilizing the current grading system have demonstrated a direct correlation with severity of primary graft dysfunction and ICU mortality, in-hospital mortality, 1-year survival, and freedom from bronchiolitis obliterans syndrome.^{64,65}

Rejection

With few exceptions, acute rejection episodes occur soon after transplantation, usually between posttransplantation days 5 and 7. Often, two or three rejection episodes occur within the first month. Mild temperature elevation, perihilar fluffy infiltrates, or a minimal decrease in blood oxygenation as measured by arterial oxygen tension may herald rejection. Because rejection occurs so frequently during this period, the distinction between infection and rejection may be difficult. Often, the distinguishing factor between these two entities is that rejection responds positively to the administration of corticosteroids. Treatment of early rejection episodes involves the use of bolus corticosteroid administration given on 3 consecutive days. Within 12 to 18 hours after the first corticosteroid dose, symptoms relating to rejection usually resolve, including clearing of infiltrates on chest radiograph.

The diagnostic experience using transbronchial biopsy to diagnose and monitor rejection at some centers after cardiopulmonary transplantation is impressive, but the number of biopsies required to maximize specificity is large. One group recommends obtaining 18 separate transbronchial biopsy specimens to achieve 95% specificity. The risks and potential complications of transbronchial lung biopsy do not justify its routine performance because suspected rejection episodes respond so well to corticosteroids. Transbronchial lung biopsy can be used when the issue of rejection versus infection is not

resolved after steroid administration. Flexible bronchoscopy can be performed at the bedside, and 6 to 10 separate biopsies can be obtained under fluoroscopic guidance. When symptoms or signs of rejection persist despite adequate treatment, open lung biopsy may be considered.

Infection

Infection in the posttransplantation period continues to be a significant cause of morbidity and mortality. Posttransplant prophylaxis strategies targeting gram-positive and gram-negative bacteria, *Pneumocystis pneumoniae*, cytomegalovirus, and *Aspergillus* have been shown to decrease the morbidity and mortality from this category of complication. Bacterial pneumonia usually responds to appropriate antibiotic therapy, and patients are maintained on broad-spectrum antibiotics until specificities are determined by culture of the donor and recipient bronchus. Antibiotic administration is particularly important if one predominant organism is grown from the donor lung cultures obtained at organ harvest. If a specific organism is grown from donor bronchial washings, the recipient is maintained on an appropriate antibiotic or combination of antibiotics for at least 1 week. The most common organism recovered from donor bronchial washings is *Staphylococcus aureus*. In a series of 32 transplants, this organism was recovered from donors 11 times and subsequently from 4 transplant recipients.⁶⁶ Other commonly recovered pathogens include *Enterobacter* species and *Candida albicans*. The presence of organisms cultured from donor bronchial washings, however, does not absolutely predict the development of invasive infection in recipients. Less than half of recipients from whom organisms were recovered went on to develop invasive infection.

The second most significant pathogen is cytomegalovirus (CMV). The diagnosis of CMV is usually made from culture of bronchoalveolar lavage fluid or tissue obtained from transbronchial lung biopsy. In the pulmonary transplantation population, CMV pneumonitis is the predominant form of CMV infection, although CMV enteritis and retinitis also occur. This experience corresponds to that seen in cardiac and cardiopulmonary transplant recipients. About half of lung recipients develop documented CMV infection. Ganciclovir has proved particularly effective and is the drug of choice for CMV infection in this circumstance. The drug is well tolerated in most patients, with neutropenia accounting for most of the toxicity. CMV prophylaxis with ganciclovir can be used for CMV-positive recipients or in those recipients who receive a lung from a CMV-positive donor. The mortality rate from life-threatening CMV infections treated with ganciclovir has been reported at 10%, far better than the 40% or greater mortality reported before this agent was available.⁶⁷ Life-threatening CMV infection can occur in CMV-negative recipients who receive a lung from a CMV-positive donor (primary infection) or in recipients who are already CMV positive (secondary infection). Cytolytic therapy especially with muromonab-CD3 is associated with an increased risk and severity of CMV infection. Attempts to match a CMV-negative recipient with a CMV-negative donor lung, given the shortage of donor organs, can prolong candidate waiting time.

A recent analysis of UNOS outcomes data demonstrated that donor–recipient CMV serologic mismatch, particularly donor-positive/recipient-negative (D+/R−) serologic status, was a significant adverse risk factor for posttransplantation mortality in earlier eras (1990–1994 and 1995–1999) but not in a more recent era (2000–2004) of pulmonary transplantation, when compared with donor-negative/recipient-negative transplants.⁶⁸ Mismatched donor–recipient CMV status also appears to be a significant univariate risk factor for mortality following retransplantation.⁶⁹ These findings suggest that donor–recipient CMV mismatch can be an adverse factor for posttransplant survival but also that this deleterious effect may

be abrogated with the introduction of more effective CMV antiviral therapy.⁷⁰

Infection with *Aspergillus* species is the most common fungal infection after lung transplant. It occurs in 15% to 35% of recipients. Overall mortality is high (52%), especially with invasive infections (80%).⁷¹ Preemptive antifungal therapy has been shown to decrease the incidence of clinical fungal infection from 69% to 31%.⁷²

Airway Complications

Airway complications can be categorized by the time course of occurrence (early vs. late) and the type of complication (stenosis, dehiscence, granulation, fistula, or infection). The incidence of airway complications has decreased substantially over time. This is likely due to improvements in lung preservation, surgical technique, and antibiotic prophylaxis.

6 During the early pulmonary transplantation experience, problems with airway healing resulted in a significant percentage of deaths. Patients often did well for the first 3 weeks after transplantation, and then the bronchial anastomosis split, often with erosion into the pulmonary artery. Bronchial anastomotic healing initially was facilitated by withholding maintenance corticosteroids until after the first posttransplantation week and using an omental pedicle wrapped around the anastomosis. Historically, most problems with airway healing occurred after the en bloc double-lung operation, which involves a tracheal anastomosis. Double-lung transplantation required extensive dissection in the subcarinal space, resulting in the disruption of a number of bronchial collateral vessels. Since this operation was modified to one involving bilateral, sequential lung replacement using two bronchial anastomoses, airway problems are infrequent and now are rarely if ever implicated in recipient deaths. Partial bronchial dehiscences often heal without sequelae.

The use of a telescoping bronchial anastomosis, in which the donor bronchus is intussuscepted into the recipient bronchus or vice versa, obviated the need for the omental pedicle wrap, allowed for immediate use of corticosteroids, and reduced anastomotic dehiscence rates. However, the telescoping anastomosis can increase the rate of anastomotic stenosis. Recently there has been a trend toward the use of primary end-to-end anastomosis using figure-of-eight sutures, and initial results demonstrate a lower incidence of stenosis with an equivalent rate of dehiscence (about 2%).^{48,49}

Bronchiolitis Obliterans

Bronchiolitis obliterans remains the leading cause of late mortality following lung transplantation, with nearly 30% of deaths beyond the first year of transplantation attributed to the fibroproliferative changes and airway destruction of this disorder. Bronchiolitis obliterans syndrome, the clinical correlate of this complication, occurs in over 40% of patients who survive beyond 90 days of operation, and remains a significant cause of morbidity, occurring in one third of patients surviving at least 5 years. Following heart–lung transplantation, nearly 50% of deaths beyond the first year are attributable to bronchiolitis obliterans and pulmonary graft failure.⁷³

Bronchiolitis obliterans syndrome is defined as decline in FEV₁ of greater than 20% from baseline, as determined by at least two separate measurements obtained at least 3 weeks apart.⁷⁴ The histologic appearance of bronchiolitis obliterans is characterized by progressive small airway destruction, airway deposition with an inflammatory exudate, and, finally, fibrosis. This complication is likely a form of chronic rejection, although its exact etiology remains unknown. If diagnosed early, enhancing immunosuppression may either halt the process or slow the progression. It has been hypothesized that the development of obliterative bronchiolitis in cardiopulmonary transplantation

patients is related to a human major histocompatibility complex (human leukocyte antigen)–A2 antigen mismatch. Others postulate that CMV infection or early lung injury, such as that arising from primary graft dysfunction,⁷⁵ may be implicated. Once diagnosed, it is imperative to increase immunosuppression to prevent what is usually an insidiously progressive disorder. Unfortunately, in patients who have developed obliterative bronchiolitis and then undergo retransplantation, the pathology can recur in the newly transplanted lungs. Obliterative bronchiolitis remains the major problem in patients surviving for greater than 2 years following transplantation. Overall, long-term survival for lung transplantation is not likely to improve significantly until effective strategies for the prevention and treatment of obliterative bronchiolitis and bronchiolitis obliterans syndrome are identified.

POSTTRANSPLANTATION PHYSIOLOGY

Pulmonary transplantation has afforded an opportunity to observe changes in pulmonary physiology that are not seen under ordinary circumstances. It is important to examine these changes relative to the type of transplantation operation.

The development of bilateral, sequential lung replacement provides the opportunity to indirectly assess lung function by perfusion lung scan. Because the newly implanted lungs have different ischemic times, the immediate posttransplantation perfusion scan would be expected to demonstrate less perfusion to the side with the longer ischemic time. Indeed, this situation does occur, especially when ischemic times exceed 6 hours; however, the relative perfusion to each side usually equalizes within 24 to 48 hours.

Performing single-lung transplants in patients with pulmonary hypertension has been particularly illustrative in demonstrating the potential for reversing right ventricular dysfunction. As soon as the lung is implanted, the morphology of the right ventricle changes significantly, as assessed by transesophageal echocardiography. The interventricular septum, previously bulging into the left ventricle, immediately assumes a normal position. An increase in contractility of the right ventricle occurs with significant decrease in dilatation. The pulmonary artery pressure immediately decreases and is essentially normal by the time the patient leaves the operating room (Table 38.7). Late catheterization studies (2 years posttrans-

TABLE 38.7 INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR PULMONARY TRANSPLANTATION

	■ SINGLE LUNG (%)	■ DOUBLE LUNG (%)
Emphysema	53.0	23.0
α_1 -Antitrypsin	8.5	9.5
Cystic fibrosis	2.3	31.0
Idiopathic pulmonary fibrosis	24.0	9.7
Primary pulmonary hypertension	1.1	7.6
Retransplant	2.0	1.7

FIGURE 38.3. Mean 6-minute walk data for a group of patients undergoing single-lung transplantations for emphysema. Marked improvement is seen at the 6-week level, with continued improvement at 12 weeks.

plantation) in patients undergoing this operation show continued normal hemodynamics.

The situation after single-lung transplantation in patients with emphysema is also illustrative. One would expect a significant ventilation/perfusion (V/Q) mismatch to occur, with ventilation to the native lung occurring preferentially because the native lung is significantly more compliant. Conversely, there is significantly greater differential perfusion to the newly transplanted lung, particularly at rest, with greater differences in perfusion observed in patients undergoing transplantation for emphysema compared with pulmonary fibrosis. With exercise, perfusion to the native lung tends to increase.⁷⁶ Despite significant perfusion to the nontransplanted lung, patients undergoing single-lung transplantation do well from a functional standpoint (Fig. 38.3) and do not typically have persistent carbon dioxide retention after transplantation. Physiologic dead space (V_D/V_T) decreases with work, with a shift in ventilation toward the transplanted side. By 3 months after transplantation, the V/Q mismatch narrows (Fig. 38.4). From a clinical standpoint, improvement in pulmonary function is seen almost immediately after transplantation. Spirometric improvement is noted within 2 weeks of operation, increasing significantly within 6 months and then remaining stable after 3 years following transplantation (Fig. 38.5). Improvement after bilateral lung replacement is slightly better.⁷⁷

Exercise studies show modest, if any, improvement after lung transplantation, with no significant differences apparent in exercise tolerance between patients with bilateral or single-lung

FIGURE 38.4. Mean values for ventilation and perfusion for patients undergoing single-lung transplantation for emphysema. Note the ventilation-perfusion mismatch that occurs, as expected, after transplantation.

FIGURE 38.5. Comparison of percentage of predicted forced expiratory volume in 1 second in 14 patients undergoing single and 10 patients undergoing bilateral sequential pulmonary transplantation for chronic obstructive pulmonary disease.

transplants.^{78,79} Maximum oxygen consumption, maximum work, peak ventilation, and anaerobic threshold are increased after lung transplantation but remain well below normal values.⁸⁰ This may be due in large part to an accompanying abnormal cardiovascular response to exercise and peripheral muscle weakness.⁸¹ By the end of the first year after transplantation, approximately 80% of recipients report no limitations in activity.⁵⁹ On average, after transplantation, the distance a patient can cover during a standard 6-minute walk test is doubled that achieved preoperatively. Recipients of bilateral lung transplants can walk farther in 6 minutes than recipients of single-lung transplants, but this difference may reflect the younger age of the bilateral transplant recipients.^{59,82}

FUTURE CONSIDERATIONS

Pulmonary transplantation has slowly evolved from an experimental therapy to standard of care for patients with respiratory failure, although many fewer patients undergo these operations compared with other solid organ transplants. Donor availability remains a limiting issue and will likely continue to be an obstacle despite efforts to improve both donor management and organ procurement efforts at a societal level. Lung volume reduction surgery has demonstrated some benefit in a select group of COPD patients but has not had as significant an impact on quality of life as lung transplant has for patients with emphysema. Questions about long-term impact and preservation of lung function remain to be answered. Other considerations including posttransplantation quality of life and cost-utility analyses also will likely impact the application of this therapy despite the accomplishments of the past 40 years.

CHAPTER 39 ■ PANCREAS AND ISLET TRANSPLANTATION

RANDALL S. SUNG

KEY POINTS

- 1 The Diabetes Control and Complications Trial demonstrated that tight control of blood glucose and minimization of hemoglobin A1C delays the progression of secondary complications of diabetes.
- 2 Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin, and pancreas transplantation has a beneficial impact on diabetic complications.
- 3 Most pancreas transplants are performed in patients with end-stage renal disease, either concomitant with or following a kidney transplant.
- 4 Pancreas transplant outcome is dependent on the careful selection of donors and on meticulous pancreas procurement technique.
- 5 Pancreas graft survival rates are greater than 80% at 1 year.
- 6 In contrast to kidney transplants, the effect of a pancreas transplant on patient survival is probably only modest.
- 7 Islet transplantation does not require an operative procedure.
- 8 Although early outcomes are excellent at major islet centers, long-term islet transplant outcomes are inferior to those of whole-pancreas transplants, with most recipients returning to insulin within 2 years.

Diabetes mellitus is a spectrum of impaired glucose tolerance that ranges from gestational glucose intolerance to severe hyperglycemia and ketoacidosis. Diabetes, which affects approximately 8% of the U.S. population, can be divided into two major classifications. Type 1, previously referred to as insulin-dependent diabetes, is an autoimmune disease characterized by the eventual loss of all pancreatic β -cell function. Type 2, previously referred to as non-insulin-dependent diabetes or adult-onset diabetes, characteristically presents in obese patients over age 40¹; many of these individuals eventually require insulin therapy. The incidence of type 2 diabetes is increasing as the prevalence of obesity increases, especially in younger age groups. While the mean age of onset is in the early teenage years, the disease may present as early as the first year of life. Type 1 diabetes afflicts approximately 1 in every 400 to 500 children and adolescents.² Patients may present as late as the fourth decade of life, and these patients may be misclassified as type 2 diabetics, despite clearly possessing the physiology of type 1 diabetes. The disease classically presents in a lean patient with polyuria, polydipsia, and polyphagia. It may present at the time of a concurrent illness. While there may be a brief “honeymoon” period after presentation where insulin is not required, exogenous insulin is always required to replace that lost by the complete destruction of β -cell mass. While hyperglycemic episodes from poorly controlled diabetes or hypoglycemic events from insulin may be life-threatening, the major morbidity of type 1 diabetes stems from the myriad long-term manifestations of the disease, particularly those that are due to accelerated atherosclerosis.

PATHOPHYSIOLOGY

The classic pathophysiology of diabetes is that of insulin secretory failure in type 1 diabetes and peripheral insulin resistance in patients with type 2 diabetes. However, the etiology, epidemiology, and pathogenesis of diabetes is much more complex than is reflected in early characterizations of the disease. Type 1 diabetes is classically described as an autoimmune disorder manifest by destruction of β -cells, with proinsulin being the

most likely primary target.³ There is multigenic susceptibility, with known genes at the human leukocyte antigen (HLA) class II genotype, the 5' flanking region of the insulin gene, and the CTLA4 gene; however, many genetic susceptibility loci have been demonstrated but not completely characterized. The possibility that these many genes may individually only have weak effects makes them more difficult to identify precisely, and may explain the heterogeneity of inheritance of type 1 diabetes. This genetic susceptibility background is thought to interact with environmental triggers, perhaps infectious, that lead to autoimmunity and insulinitis, the characteristic pathologic lesion of type 1 diabetes, although definitive proof of these triggers is lacking. In type 2 diabetes, while β -cell hypersecretion initially may exist, ultimately loss of β -cell mass ensues. β -Cell apoptosis is mediated by glucotoxicity from insulin resistance, and is exacerbated by fatty acids, lipoproteins, leptins, and cytokines, all of which are elevated in type 2 diabetes and obesity.⁴ Because of peripheral insulin resistance, many patients require insulin in amounts that exceed 1 unit/kg, far greater than typically required by type 1 diabetics.

The observation that type 1 and type 2 diabetes frequently co-occur in the same family has raised the possibility that they are opposite ends of the same disease spectrum, and ample evidence exists that suggests the two are more similar than initially believed.^{5,6} Families with mixed diabetes histories tend to have an intermediate diabetes phenotype: insulin resistance in type 1 and lower body mass index (BMI) and C-peptide concentrations in type 2 patients. β -Cell destruction is common to both types, and obesity and insulin resistance have both been shown to be risk factors for childhood type 1 as well as type 2 diabetes. The “accelerator hypothesis” of diabetes proposes three determinants of disease in all types of diabetes: the intrinsic rate of β -cell apoptosis, insulin resistance, and autoimmunity (which would apply only to a subset). Genetic studies suggest there may be a common predisposition. However, the cytokines, signal transduction pathways, and other soluble mediators of apoptosis are quite different between the insulinitis of type 1 diabetes and the lipotoxic or glucotoxic processes of type 2 diabetes, and thus at minimum represent distinct mechanisms of β -cell destruction.⁷

The relatively recent discovery of the replicative potential of a variety of adult tissue types, and their roles in the pathogenesis of disease, has raised questions about the relevance to the pathogenesis of diabetes. In such a model, diabetes occurs due to a failure of regeneration of β cells, and individual variation in the ability to regenerate β cells is an important determinant of diabetes development. This is partially supported by the finding of associations of type 2 diabetes with genes having identified roles in cellular development. While it is broadly agreed that failure of β -cell replication is an important contributor to diabetes development, this is largely attributed more to an increased susceptibility of replicating β cells to apoptosis, which in a proapoptotic environment leads to loss of β -cell mass, rather than individual variations in replication. There is also evidence that deficits of β -cell secretion are as important as those of replication. Furthermore, the range of β -cell mass in adult diabetic and nondiabetic humans is very wide, and exceeds the apparent capacity for expansion of β -cell mass in response to regenerative stimuli. Thus, it appears more likely that insufficient growth of β -cell mass during development may be more likely to have a role in the predisposition to diabetes than specific deficits in regeneration.⁸

SECONDARY COMPLICATIONS OF DIABETES

Diabetes mellitus is responsible for tens of thousands of deaths each year in the United States. The high incidence of cardiovascular complications in diabetics is primarily responsible for the twofold increase in the risk of death in diabetics compared with those without diabetes.² Clinical complications of diabetes include end-stage renal disease, retinopathy, peripheral vascular disease, coronary artery disease, and neuropathy. Diabetic nephropathy is responsible for nearly half of all cases of end-stage renal disease; diabetes is also the leading cause of blindness and amputations in the United States.⁹ The estimated cost of providing care for diabetes and its complications is over \$150 billion per year.¹

While diabetic complications have a multifactorial etiology, they are ultimately secondary to structural alterations in nerves, blood vessels, and connective tissue. Excess glucose is converted to sorbitol by aldose reductase, leading to the reduction of cellular content of myoinositol, abnormal phosphoinositide metabolism, and reduction in Na^+ - K^+ -adenosine triphosphatase (ATPase) activity. In experimental animals aldose reductase inhibitors prevent diabetic neuropathy, cataracts, and retinopathy.¹⁰ The accumulation of advanced glycosylation end products (AGEs), due to abnormal nonenzymatic glycosylation of proteins and extensive cross-linking of these proteins, is likely to be pathogenic.¹¹ Ligation of endothelial cell receptors by AGEs results in the release of proinflammatory cytokines and activation of the coagulation cascade. Microangiopathy is characterized by thickening of capillary basement membranes, which increases with the duration of disease, and altered capillary permeability.

- 1 The Diabetes Control and Complications Trial (DCCT) demonstrated that tight control of blood glucose prevents and delays the progression of secondary complications of diabetes.^{12,13} This study, in which patients with type 1 diabetes were randomized to conventional treatment with one or two doses of daily insulin versus intensive treatment with three or more injections per day, demonstrated a dramatic reduction in the risk of progression of retinopathy, microalbuminuria, albuminuria, peripheral neuropathy, and cardiovascular disease in the subjects randomized to intensive treatment. However, the major side effect of intensive treatment was a threefold increase in the risk of severe hypoglycemic episodes; approximately 10% of patients in the intensive insulin therapy cohort experienced five or more episodes of seizure or coma during the study

period. Even in the absence of overt brain injury, multiple episodes of severe hypoglycemia have been associated with cerebral perfusion abnormalities and poor neuropsychiatric performance. In addition, there is a significant risk of accident during hypoglycemic episodes. Frequently, as hypoglycemia becomes more frequent and autonomic neuropathy worsens, patients may develop a syndrome of unawareness to hypoglycemia where the typical symptoms of tremor and anxiety do not occur. Such patients with hypoglycemic unawareness may develop profound hypoglycemia, especially if left unsupervised, and risk severe neurologic and traumatic injury.

The overall management of diabetes is focused on maintaining blood glucose as close to normal range as possible while attempting to minimize significant hypoglycemic episodes. Although the frequency and extent of hyperglycemia is important in the assessment of glucose management, long-term glycemic control is best assessed by evaluation of blood levels of hemoglobin A1C, which measures the extent of glycosylation of hemoglobin. Although the incidence of diabetes is increasing, the overall treatment efficacy has improved. The use of subcutaneous insulin pumps is being increasingly employed; inhaled insulin has been used in selected patients; and infusion devices, which also assess serum glucose and automatically adjust insulin dose accordingly, are being developed.^{14,15} However, in practice it is a rare diabetic who can maintain tight glucose control without hypoglycemic complications. In fact, in a study of type 2 diabetics designed to reduce cardiovascular complications through normalization of glycemic control, intensive therapy was associated with increased early mortality and no reduction of cardiovascular events.¹⁶ Most type 1 diabetics, even if on optimal insulin therapy, are unable to maintain hemoglobin A1C levels in the normal range, and most will ultimately develop progressive diabetic complications.

PANCREAS TRANSPLANTATION

Overview

Pancreas transplantation, while not technically a cure, represents the only option for insulin elimination for many type 1 diabetics. Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin. Initial experience with pancreas transplantation, from the first pancreas transplant performed by Kelly and Lillehei in 1966 until the 1980s, was marked by low success rates and high mortality.¹⁷ In 1980, the 1-year graft survival rate for pancreas transplantation was only 21%, and there was tremendous skepticism about the utility of the procedure prior to the advent of cyclosporine. Advances in surgical technique and immunosuppression have dramatically improved current graft survival rates to greater than 85% at 1 year. In addition to the development of cyclosporine, the introduction of bladder drainage of the donor pancreas, first introduced by Sollinger in 1985 using a button of donor duodenum, and subsequently modified by Corry in 1986 using an entire segment of duodenum anastomosed to the urinary bladder, dramatically improved the results of pancreas transplantation (Fig. 39.1).^{18,19} Graft survival continued to improve throughout the 1980s and 1990s, especially for isolated pancreas transplantation (pancreas transplant alone, or pancreas after kidney transplantation), the results of which have been historically inferior to simultaneous kidney-pancreas transplants. Both short- and long-term survival of pancreas transplants has remained relatively stable in the current decade. Because bladder drainage is associated with significant morbidity, in recent years there has been a shift toward enteric drainage into the recipient jejunum. Currently, most pancreas transplants are performed with enteric exocrine drainage and venous drainage into the systemic circulation. However, pancreas transplantation

FIGURE 39.1. Simultaneous pancreas–kidney transplantation performed with drainage of the pancreatic exocrine secretions into the urinary bladder (bladder drainage). This technique has been predominant until recently. Note that a segment of the second portion of the duodenum is left attached to the pancreas. Despite its heterotopic location, the transplanted pancreas responds to gastrointestinal hormones with a marked increase in secretion of pancreatic juice that has very high bicarbonate content. Also note that the portal vein drains into the iliac vein (i.e., systemic venous drainage). In healthy individuals 50% of the secreted insulin is extracted from the circulation in the first pass through the liver. Transplant recipients with systemic venous drainage have peripheral insulin levels two to two and one half times higher than normal.

may also be performed by draining pancreatic venous blood into the recipient portal circulation, usually via the superior mesenteric vein.

Patient Selection

Pancreas transplantation is usually performed in patients with type 1 diabetes. The diagnosis of type 1 diabetes is relatively straightforward for most individuals. A history of juvenile or young adult onset, diabetic ketoacidosis, a lean body habitus, and a low insulin requirement (<0.7 units/kg) all support the diagnosis of type 1 diabetes. In contrast, older age of onset, obesity, an interval of treatment with diet or oral agents, or high insulin requirements are all suggestive of type 2 diabetes. A subset of adult-onset diabetics will display characteristics otherwise associated with type 1 diabetes, including absence of insulin production. Whether these individuals are properly classified as type 1 or type 2 diabetics may be subject to debate, but these individuals may certainly benefit from pancreas transplantation. Individuals with type 1 physiology but adult age of onset and low but detectable C-peptide secretion (so-called “type 1.5 diabetics”) may also be considered for pancreas transplantation. Approximately 5% of pancreas transplant recipients are reported as having type 2 diabetes, and outcomes for these recipients are similar to those with type 1 diabetes.²⁰ These are likely to be highly selected individuals without significant insulin resistance; most type 2 diabetics would not be considered candidates. Some type 1 diabetics may develop

insulin resistance as a result of years of insulin therapy; this is frequently accompanied by increased body weight and insulin requirements. While such patients, if transplanted, may be helped by oral agents typically used for type 2 diabetics, they are at higher risk for remaining on insulin after pancreas transplantation.²¹ While provocative tests for insulin resistance exist, they are not commonly employed.

A small percentage of pancreas transplant recipients do not have type 1 diabetes, but have diabetes from other causes. Several have undergone pancreatectomy for chronic pancreatitis or other conditions.²² Some pancreas transplants ($<1\%$) are performed as part of a multivisceral transplant that includes liver and small intestine in patients who do not have diabetes; in these transplants, the pancreas is included in the graft to facilitate the technical conduct of the operation and to reduce complications.²³

- 3 Most individuals evaluated for pancreas transplantation have chronic renal disease. These patients may present prior to onset of dialysis, while currently receiving dialysis, or following kidney transplantation. For individuals without a functioning kidney transplant, potential options include simultaneous deceased donor kidney–pancreas transplantation (SPK), living donor kidney transplantation followed by deceased donor pancreas transplantation (PAK), simultaneous living donor kidney–deceased donor pancreas transplantation (SPLK), or simultaneous living donor kidney–pancreas transplantation. Of these options, the former two are by far the most common.

Simultaneous Kidney–Pancreas Transplantation

SPK from a deceased donor is the most commonly performed pancreas transplant option, with the number exceeding all other types combined. An SPK transplant has the advantage of requiring only one operation for both transplants. Since alloreactivity against the transplanted pancreas tends to be concordant with activity against the kidney, pancreas rejection may be heralded by signs of kidney rejection, which are more sensitive and present earlier. Consequently, SPK pancreas outcomes have been historically superior to those of solitary pancreas transplants.

Pancreas after Kidney Transplantation

If a living kidney donor is available, candidates have the option of receiving a living donor transplant, followed by a deceased donor pancreas transplant. This approach has the disadvantage of requiring two separate operations, but the recipient enjoys the benefit of a living donor kidney transplant that in many circumstances occurs sooner than would an SPK from a deceased donor. Since the primary survival benefit of the kidney–pancreas transplant comes from the restoration of renal function, this is a significant advantage. However, since a PAK is essentially a solitary pancreas transplant immunologically distinct from the kidney transplant, pancreas outcomes are worse than for SPK.

Simultaneous Living Donor Kidney–Deceased Donor Pancreas Transplantation

SPLK is another option performed at a few centers.²⁴ Candidates with identified living donors are listed for deceased donor pancreas transplantation. When a deceased donor pancreas becomes available, the living kidney donor transplant is performed at the same time as the pancreas transplant. This approach has the advantages of sequential living donor kidney followed by PAK transplants while requiring only one operation.

It does require that the potential living donor be available around the clock, a requirement that excludes some donors from this approach. It also has the disadvantage of potentially delaying a kidney transplant for the recipient if the waiting time for a deceased donor pancreas is long. However, since waiting times for solitary pancreas in some areas of the country can be quite short, the advantages may be substantial.

Living Donor Kidney–Pancreas Transplantation

A few centers perform living donor kidney–pancreas transplantation, with a single living donor donating the tail of the pancreas as well as the kidney (Fig. 39.2). This approach has

all the advantages of a single operation, a single donor, and no waiting time. Results have been comparable to deceased donor SPK transplants.^{25,26} Widespread adoption of this approach has been limited by concerns about donor morbidity from the pancreatectomy. Serious complications such as pancreatitis, fistula, abscess, or pseudocyst occur in nearly 10% of pancreas donors. Glucose intolerance and frank diabetes have occurred, although this problem has largely abated with more stringent donor selection criteria.²⁶

Pancreas transplant candidates with renal failure may be counseled in a variety of ways depending on the availability of a living donor. How individuals are counseled depends in part on factors particular to the potential living donor and recipient, and also on the expected waiting time for SPK and PAK transplantation, which vary greatly by geographic region.

FIGURE 39.2. Live donor pancreas and kidney transplantation. **A:** Provided that the donor has a normal glucose tolerance test, a living donor may donate the segment of the pancreas that is to the left of the superior mesenteric vessels. **B:** Transplantation of the tail of the pancreas is based on the splenic artery and vein.

Since the mortality benefit of a kidney-pancreas transplant derives primarily from the kidney transplant, priority is generally given to achieving kidney transplantation expeditiously. In geographic regions where the waiting time for SPK is long (5 years is not unusual), living donor kidney transplantation is advised. Recipients of living donor kidney transplant can then be listed for PAK, which can be performed following recovery from the living donor kidney transplant. Individuals without living donors or those with borderline living donors in areas with short waiting times can be listed for SPK.

Pancreas Alone Transplantation

A small number of type 1 diabetics are evaluated for pancreas transplantation alone (PTA). These individuals are generally extremely labile diabetics who have progressive complications but do not have nephropathy. In these individuals the risk-benefit equation is quite different than that of uremic diabetics evaluated for kidney-pancreas transplantation. For nonuremic diabetics evaluated for pancreas transplantation the risk of immunosuppression in addition to the surgical procedure must be weighed against the potential benefits from transplantation. This contrasts to uremic diabetics, where the risk of immunosuppression is already assumed by virtue of the need for a kidney transplant. As will be discussed later, whether pancreas transplantation alone for type 1 diabetes results in a significant mortality benefit is controversial. For this reason, pancreas transplantation alone in most centers is generally offered only in the most exceptional cases, the most common indication being frequent life-threatening hypoglycemic events. However, several transplant programs exist that have a different philosophical outlook on the benefits of PTA, and these referral centers generally perform large numbers of PTAs. Most PTAs are from deceased donors, with a small number of centers offering living donor PTAs.

Evaluation and Screening

In general, eligibility criteria for pancreas transplantation are more stringent than for kidney transplantation alone, since the operation and potential complications are more stressful and the benefits less pronounced compared with kidney transplantation. All candidates, in addition to assessment of the potential benefit of pancreas transplantation, should have at the least noninvasive cardiac stress testing such as dobutamine stress echocardiography or adenosine thallium stress scintigraphy. Potential candidates with reversible myocardial defects should undergo coronary angiography, and many centers perform angiography on all candidates. The decision to perform pretransplantation coronary revascularization, either with angioplasty, stenting, or bypass, must be made with consideration of both peritransplant mortality and long-term survival. Although practices vary, a history of coronary revascularization is not necessarily a contraindication; individuals with extensive myocardium at risk and without revascularization options are frequently excluded.

Screening for peripheral vascular occlusive disease is often performed. Although distal peripheral vascular occlusive disease is characteristic of longstanding diabetes, aortoiliac disease and femoral popliteal vascular disease may also be present. Mild femoral popliteal disease is generally not a contraindication to transplantation, unless there are clinical signs of arterial insufficiency such as severe claudication or nonhealing ulcers. The presence of iliac disease is more problematic, as it can compromise inflow to the transplanted organs or increase the risk for postoperative arterial complications. In addition, diabetics may have significant vascular

calcification, which could preclude transplantation even in the absence of flow abnormalities. Screening for peripheral vascular occlusive disease, in addition to a thorough physical exam, may include noninvasive flow studies, magnetic resonance angiography, conventional angiography, and pelvic radiography and/or computed tomography (CT) scanning to evaluate vascular calcification. Candidates with a history or exam findings suggestive of cerebrovascular disease should be screened for hemodynamically significant carotid occlusive disease.

Other evaluations, as with other types of transplant, are tailored to the individual medical history, and differ among centers. Screening for malignancy commonly includes mammography and Pap smears for women, prostate-specific antigen levels in men, and colonoscopy. Individuals with a prior history of treated cancer and who are judged to be at low risk for recurrence are usually candidates following an appropriate disease-free interval. This interval is decreasing as greater experience with transplantation in individuals with a history of cancer has accumulated, and can be as little as 2 years for many solid epithelial tumors to none for carcinoma in situ.²⁷ Screening for chronic viral infections such as hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) is commonly performed, and pancreas transplants in selected individuals with chronic hepatitis are being performed with increasing frequency.^{28,29} Although experience with liver and kidney transplantation in carefully selected individuals with HIV infection has been encouraging, this experience has not yet been applied to pancreas transplantation.³⁰ Social work and/or psychiatric evaluation is performed to rule out psychiatric disease, inadequate social environments, and other issues that may impact the recipient's ability to participate in post-transplantation management.

The Kidney-Pancreas Waiting List and Recipients

The number of patients on the waiting list for a simultaneous kidney-pancreas transplant decreased from 2,451 in 2000 to 2,416 in 2006.³¹ The majority of patients are white (68%), though the percentages of white and African-American (16%) candidates are decreasing, while the percentage of Hispanic/Latino patients (12%) continues to increase. The number of patients on the waiting list has decreased since 2000 for all adult age groups except those 50 to 64, and the age distribution has shifted upward. While the majority are ages 35 to 49 (59% in 2006), the percentage who are ages 50 to 64 is increasing (22% in 2006) and the percentage who are ages 18 to 34 (19% in 2006) is decreasing. The annual death rate on the SPK waiting list was 97 per 1,000 patient-years in 2006; while this rate varies from year to year, the trend has not changed over the past decade.

After a steady decrease in the number of SPK transplants performed, from a peak of 970 in 1998 to 871 in 2003 (Fig. 39.3), the number increased again to 924 in 2006. This increase corresponds to a decrease in solitary pancreas transplants. This could represent a trend away from performing PAK transplants among the transplant community, or it may represent recent changes in local allocation policies that favor performance of SPK transplants. Median times to SPK decreased to 451 days for registrants listed in 2005, from a peak of 543 days for registrants listed in 2000. Time to transplant is longer for African-American and Hispanic/Latino recipients. While the majority of SPK recipients are white (75%) and male (65%), the percentage of SPK recipients who are African-American increased from 9% in 2000 to 15% in 2006; those who are Hispanic increased from 5% to 8% over the same period. The age distribution of recipients parallels that of the waiting list.

FIGURE 39.3. Number of U.S. simultaneous pancreas-kidney (SPK), pancreas after kidney transplantation (PAK), and pancreas transplantation alone (PTA) transplants performed by year. (Data from Scientific Registry of Transplant Recipients. 2007 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2008.)

The Pancreas Transplant Waiting List and Recipients

The number of patients awaiting isolated pancreas transplants in 2006 continued to increase, with 609 patients awaiting PTA versus 412 in 2002, and 1,007 awaiting PAK versus 786 in 2002.³¹ The increase in the number of patients waiting for isolated pancreas transplants in the last 5 years is largely due to a decrease in the numbers of transplants performed rather than an impact of new registrations, which increased modestly for PTA but has decreased for PAK.

The great majority of patients awaiting isolated pancreas transplants are white (83% for PTA, 81% for PAK); there have been significant increases in the percentage of African-Americans on the PAK and PTA lists over the last several years. Although women continued to constitute 57% of the PTA waiting list in 2003, they were only 46% of the PAK waiting list. The majority of patients awaiting both PTA and PAK are between 35 and 49 years old, but as with SPK candidates, the percentage of older patients listed for PAK and PTA has increased, with 16% and 22%, respectively, of the waiting list in 2006 being between the ages of 50 and 64 years.

The median time to transplant for PAK has gradually increased over the last 5 years, with the mean waiting time for candidates registered in 2004 being 562 days. This is greater than the median time to transplant for SPK registrants. Wait times for PTAs have remained around 1 year since 2002, which suggests that solitary pancreata are more available than SPKs. PAK and PTA patients with blood group types O and B have historically had longer waiting times than those with types A and AB, a pattern observed in both kidney and SPK recipients.

The age and race of recipients of solitary pancreas transplants reflect the waiting list. In 2006, 88% of PAK and PTA recipients were white, reflecting an ongoing disparity in racial distribution of solitary pancreas transplants, which is even more marked than that for SPK transplants. The reasons for this disparity are uncertain, but likely reflect access to these procedures. More PAK recipients (54%) were male, but more PTA recipients (54%) were women, although the gender gap has closed in the past 5 years. The age at transplant has remained relatively consistent over the last several years, with a slight shift to younger patients receiving PTA.

Deceased Donor Pancreas Allocation

As with many organs, deceased donor pancreas allocation is determined primarily by geography, with most organs offered to centers in the donation service area (DSA) of donor origin. The base organ allocation unit is the organ procurement orga-

nization (OPO), which serves the population within the DSA. The 58 DSAs are organized into 11 regions, which serve as the second tier of organ allocation. In contrast to other organs, however, most pancreata are allocated according to locally determined policies set by the OPO; however, certain national rules exist.³² There is mandatory sharing of pancreata to highly sensitized candidates that are completely matched to the donor. SPKs are allocated to these kidney-pancreas candidates first locally, then regionally, then nationally. If the pancreas is not allocated to an SPK candidate, then the solitary pancreata are similarly allocated to completely matched candidates.³²

A number of utilization issues specific to pancreas transplantation influence allocation. Pancreata are significantly underutilized compared to other solid organs such as liver and kidney. Restrictions on cold ischemia time for whole-pancreas transplantation and particularly for islet transplantation make the placement of pancreata that are not used by the recovering center difficult. There is significant geographic variation in pancreas use, which correlates with activity by local transplant centers.³³ The allocation of pancreata is also complicated by the fact that pancreas donor selection criteria for islet transplant and whole-organ transplant overlap, leading to competition among certain types of pancreata. Allocation of kidneys to SPK candidates prevents allocation to kidney-alone candidates. This may lead to disagreement between transplant centers with and without pancreas transplant programs over allocation policies. Solitary pancreata are more difficult to place compared with SPK because their outcomes are slightly worse, but are more easily shared voluntarily since OPOs have no obligation to share kidneys along with pancreas for outside SPK candidates; since pancreas donors are carefully selected, the kidneys from these donors are usually able to be transplanted into a local kidney candidate.

In determining whether a given pancreas will be allocated to a solid organ or islet transplant candidate, donor age and BMI are considered. Donors under age 50 and with a BMI less than 30 are allocated for whole-organ pancreas transplant locally. If there is no local acceptance, the pancreas is offered regionally and then nationally. If there is no candidate for whole pancreas, the pancreas is then allocated for islets. For donors older than age 50 or with a BMI greater than 30, whose pancreata are rarely used for whole-organ transplant, the organ is first offered for pancreas transplant locally; if there are no local candidates, the pancreas is then offered for islets.³²

Local policies vary widely. In some OPOs, SPK candidates have priority over candidates for isolated pancreas transplant, which increases the numbers of SPK and thus the overall benefit from transplantation to pancreas transplant candidates. In addition, because SPKs are easier to place, it is believed that this increases overall pancreas utilization. In other localities

isolated pancreas transplant candidates receive priority. This is meant to encourage living donor kidney transplant by shortening wait times for PAK, and to decrease the disparity in waiting times between SPK and kidney-alone candidates. Within groups, status on the waiting list is determined by waiting time. In other systems no priority is given, but place on a combined SPK/PAK/PTA waiting list is determined by waiting time only.

Pancreas allocation is also influenced by how candidates are prioritized on the kidney transplant waiting list. In some cases, the kidney follows the pancreas; in other words, a kidney transplant is allocated to SPK candidates regardless of their place on the kidney list. This is thought to increase pancreas utilization by encouraging allocation of combined kidney-pancreas. This practice is also consistent with that applied to other multiorgan transplants such as heart-kidney and liver-kidney. Some OPOs will preferentially allocate kidneys to higher-priority kidney transplant candidates, such as highly sensitized or pediatric candidates, over SPK candidates. In other OPOs the pancreas follows the kidney; that is, pancreas allocation for an SPK candidate is dependent on the kidney match run. Since waiting times for kidney candidates exceed that for pancreas candidates, this tends to discourage SPK.

Donor Evaluation

4 The selection of appropriate pancreas donors is perhaps the most important determinant of successful pancreas transplantation. Many of the early complications of pancreas transplantation are thought to be secondary to processes related to organ quality and preservation, rather than the technical conduct of the recipient operation. While the ideal donor is young, nonalcoholic, and nonobese, very few donors meet this description, and the surgeon frequently needs to consider pancreata from imperfect donors. Donor selection criteria may vary among surgeons and transplant centers, and may depend on past experience, waiting time, and recent outcomes. Primary criteria are the age of the donor, donor BMI, donor cause of death, and gross appearance of the organ at the time of recovery. Additional information that may influence the decision includes aspects of the medical and social history, donor hemodynamics, laboratory values, HLA matching, and anticipated preservation time. As with donor selection with other organs, the decision-making process often involves consideration of multiple factors in aggregate.

The importance of donor age on graft outcomes has been confirmed by multiple studies, and the maximum age threshold is significantly lower than for liver and kidney transplantation.^{34,35} Many centers use an age threshold, which may range from 40 to 50, above which donors are selected very carefully. Only 7% of pancreas transplants in 2006 were from donors over the age of 50.³¹ The mechanism by which age affects outcomes is not firmly established: age appears to influence both early technical and late graft loss.^{35,36}

Donor BMI has been found to be a determinant of graft failure by single-center and transplant registry analyses.^{37,38} Very few pancreata from donors with BMIs greater than 30 are used for solid organ transplant, and are more likely to be recovered for islet transplant.³³ Interestingly, for overweight but not obese donors (BMI 25 to 30), a large single-center study found a higher rate of technical failure for donors that also had a cerebrovascular attack as cause of death.³⁷ It is not known whether associations with BMI relate to fatty infiltration of the pancreas or a separate mechanism.

The circumstances of death and the condition of the donor influence donor selection. Pancreata from donors with stroke as a cause of death have reduced graft survival. Although experience from donors after cardiac death (DCDs) is limited, a small number of centers have published good outcomes with careful donor selection.^{39,40} Laboratory values, including

serum amylase and lipase, play a relatively minor role in donor selection. Insulin administration is generally not considered a contraindication to pancreas donation. While the presence of donor hyperglycemia may raise concerns about latent diabetes, in most donors this reflects the rapid administration of dextrose-containing solutions, corticosteroids for cerebral edema, and high-dose catecholamines for blood pressure support rather than latent pancreatic endocrine insufficiency. Abnormal HbA1C has been utilized as a relative contraindication, but is not well studied and is not uniformly available for use. Evidence of injury to other organs such as liver and kidneys as a marker of abdominal ischemia, while not ordinarily a contraindication, may be considered in marginal cases.

Donors with a history of type 2 diabetes, excessive alcohol use, or pancreatitis may be used. A history of cardiovascular disease or cardiac risk factors are also not contraindications but may influence decision making or be associated with mesenteric atherosclerotic disease. A social history that suggests an increased risk of transmission of hepatitis or HIV should be evaluated, as with other organs, in the context of the degree of perceived risk relative to the benefit of the transplant.

Intraoperative evaluation of the donor organ is said to be the most important determinant of donor selection. Evidence of inflammation or fibrosis, which may manifest as focal or diffuse firmness to palpation, is considered to be a contraindication. Fatty infiltration of the pancreas, trauma, and pancreatic edema are also adverse findings, although the latter may be correctable with donor management. Traumatic injury to the pancreas or hematoma within the substance of the pancreas would preclude transplantation. However, a prior splenectomy is not a contraindication, provided that the tail can be dissected atraumatically.

Factors not intrinsic to the donor may bear on the decision to perform a transplant. The higher risk of graft failure—associated solitary pancreas transplants leads some centers to have more stringent selection criteria for PTA and PAK. While little data exist to suggest a definitive effect of cold ischemia, in practice shorter times are preferred, and those transplanted with clinical islet transplantation approaching 24 hours are more likely to be carefully selected. Attention to HLA matching varies widely by center; the many analyses performed suggest that any relationships between matching and graft outcome that may exist are not likely to be very significant.^{36,38,41}

Procurement Technique

The importance of the pancreatic procurement cannot be overstated. It is thought by many pancreas transplant surgeons to be more critical to the success of the transplant than the recipient procedure. Because the pancreas is susceptible to traumatic injury, it must be carefully dissected and manipulated to avoid injury to the pancreatic parenchyma. Typically the pancreas is procured along with the liver and kidneys. This is performed in standard fashion through a midline incision that extends from the sternal notch to the pubic symphysis. After a generous Kocher maneuver, mobilization of the right colon, and isolation of the distal and supraceliac aorta to prepare these vessels for clamping, the pancreas is mobilized. This is most commonly achieved by entering the lesser sac, dividing the gastrocolic omentum. This dissection continues with division of the short gastric vessels and the avascular gastrosplenic ligament. The pancreas is dissected from the pancreatic bed using the spleen as a handle. The tail is lifted from the pancreatic bed using blunt dissection and the occasional use of electrocautery. The proximal jejunum is dissected at the ligament of Treitz. An antibiotic and/or Betadine-containing solution is frequently instilled into the duodenum through a nasogastric tube for decontamination. The duodenum is divided both at the ligament of Treitz and at the pylorus using a stapler. Division of the middle colic vessels permits exposure of the proximal small

FIGURE 39.4. Back-table preparation of the pancreas. Before transplantation, the pancreas must be prepared in a slush-filled basin to maintain cold preservation. Preparation includes unifying the arterial blood supply of the pancreas by anastomosis of the donor external iliac artery to the superior mesenteric artery and the donor internal iliac artery to the splenic artery. The donor common iliac artery is used for anastomosis to the recipient iliac artery. During back-table preparation, donor splenectomy is performed.

bowel mesentery, which is divided distal to the pancreas with a vascular stapler. The mobilization of the pancreas may be performed either prior to or following the aortic perfusion procedure described later.

Perfusion of the pancreas is generally achieved through an intra-arterial cannula placed in the distal aorta following clamping of the supraceliac aorta and the aortic bifurcation. This is typically achieved with approximately 3 L of University of Wisconsin solution while the entire abdominal organs are packed in saline slush. Recent experience with HTK (histidine-tryptophan-ketoglutarate) in pancreas transplantation suggests no increase in risk of adverse outcomes with use of this preservation solution.^{38,42} Some centers will also perfuse the abdominal viscera with a portal perfusion cannula, typically through the inferior mesenteric vein, although some surgeons maintain that overperfusion of either the arterial or particularly the venous circulation may result in pancreatic edema and an increased risk of complications.

The pancreas can be removed either en bloc with the liver and kidneys, en bloc with the liver, or separately, following removal of the liver. Whatever the technique, the portal triad is dissected out in cooperation with the liver procurement team. Typically the portal vein is shared by dividing it at the level of the coronary vein. Only in the rarest of circumstances should there be any difficulty using both the liver and the pancreas from the same donor even in the presence of hepatic arterial anomalies. In the presence of a replaced right hepatic artery, the superior mesenteric artery can be divided just distal to the replaced right hepatic artery, leaving a very short cuff of superior mesenteric artery on the pancreas. Alternatively, the replaced right hepatic artery, if large enough to be safely reconstructed by the liver transplant team without a cuff of superior mesenteric artery, can be transected as it exists superiorly from behind the head of the pancreas. The bile duct and gastroduodenal artery are ligated on the pancreas side and divided on the liver side. Dissection then proceeds along the superior aspect of the pancreas along the proper hepatic artery. The splenic artery, which constitutes the other arterial blood supply to the pancreas, is divided a few millimeters from its origin to allow for adequate length on the pancreas while allowing the stump to be oversewn without compromising flow to the liver. Once the pancreas is removed or split from the liver, the pancreas is packed in preservation solution; the entire common iliac artery and its two main branches, the internal and external iliac arteries, are packaged along with the pancreas for back-table reconstruction. A graft of donor iliac vein is also included in case the portal vein needs to be extended, which is done by some surgeons. Although most centers transplant the pancreas as soon as possible, up to 24 hours of cold ischemia time (time between perfusate infusion and organ reperfusion) has not been associated with reduced graft survival.³⁶

Back-table Preparation of the Pancreas

The pancreas is placed on ice and remains cold at all times on the back table. The spleen is removed by dividing all vessels near the spleen, taking care to avoid injury to the tail of the pancreas, which should be clearly identified. Some surgeons elect to wait until reperfusion of the pancreas in the recipient to remove the spleen. Significant peripancreatic fat, if left on at the time of procurement, should be trimmed. Both ends of the distal duodenum are shortened to the point where they are immediately adjacent to the head of the pancreas. Both stapled ends of the duodenum may be oversewn with silk or polypropylene sutures. Some surgeons elect to reinforce the mesenteric staple line by oversewing with polypropylene suture. The iliac artery Y-graft is typically attached by anastomosis of the internal iliac artery to the splenic artery and anastomosis of the external iliac artery to the superior mesenteric artery (SMA, Fig. 39.4). In the absence of a Y-graft, the splenic artery may be implanted in end-to-side fashion to the SMA. The portal vein is mobilized by freeing from surrounding adventitial tissue to the confluence of the splenic vein and superior mesenteric vein. This should allow an adequate length of portal vein for anastomosis, as only 1 to 2 cm of portal vein length is generally needed.

Recipient Operation

The pancreas transplant is typically performed through a mid-line incision, although a lower quadrant incision similar to a kidney transplant incision may be used. The recipient should receive broad-spectrum antibiotics preoperatively. The pancreas transplant, for systemic venous drainage, is placed in the iliac fossa, preferably on the right side. After dissection of the iliac artery and vein, the portal vein is anastomosed in an end-to-side fashion to the external iliac vein. The common iliac vein or distal inferior vena cava may also be used; the recipient vein segment should be mobile enough for the portal vein to reach without tension. The common iliac artery component of the donor Y-graft is then anastomosed in an end-to-side fashion to either the recipient external iliac artery or common iliac artery; the distal aorta can also serve as the site of anastomosis. A pancreas placed on the left side in the recipient may be placed either medial or lateral to the sigmoid colon. Multiple variations have been described.

Because of concerns about the systemic hyperinsulinemia that invariably develops with systemically drained pancreas transplants, portal venous drainage is also utilized (Fig. 39.5). As 50% of insulin is removed with the first pass through the liver, systemic drainage leads to elevated peripheral insulin levels, which is not observed following portal venous drainage. Since hyperinsulinemia has been associated with dyslipidemia

FIGURE 39.5. Simultaneous pancreas–kidney transplantation performed with drainage of the pancreatic exocrine secretions into the proximal jejunum (enteric drainage). This technique has been adopted by most transplant centers in the United States for simultaneous pancreas–kidney transplants. For solitary pancreas transplantation, some centers still utilize bladder drainage to allow monitoring of the urinary amylase. Note that the donor portal vein drains into the recipient superior mesenteric vein (portal venous drainage), preventing peripheral hyperinsulinemia. Many centers continue to place the pancreas in the pelvis, combining enteric drainage and systemic venous drainage. This placement requires enteric anastomosis to a more distal segment of jejunum or ileum.

and accelerated atherosclerosis, portal venous drainage theoretically ought to decrease cardiovascular risk compared with systemic drainage.⁴³ Portal drainage is associated with stimulation of the insulinlike growth factor I (IGF-I)/growth hormone (GH) axis, contributing to glucose control despite lower insulin levels.⁴⁴ However, despite a nearly 10-year experience with the procedure, no effect on cardiac morbidity or mortality has been shown, although equivalent graft and patient survival has been demonstrated.^{45,46}

Although the type of venous drainage typically depends on the preferences of individual surgeons or transplant centers, the decision to perform portal or systemic drainage may also depend on the anatomy of an individual patient. Patients with multiple previous abdominal operations or who have a thickened mesentery may be more suited for systemic venous drainage. Alternatively, patients who have had multiple transplants or other operations on the iliac vessels may be candidates for portal venous drainage.

For portal venous drainage the superior mesenteric vein is dissected out just below the transverse mesocolon.⁴⁷ The right common iliac artery is almost completely dissected. An end-to-side anastomosis of the donor portal vein to the recipient superior mesenteric vein is performed with the duodenum oriented superiorly and the tail pointed inferiorly. The iliac artery graft

of the donor is then passed through a hole created in the small bowel mesentery and anastomosed to the recipient common iliac artery.

Most centers currently use enteric exocrine drainage for simultaneous kidney–pancreas transplant and some centers use enteric drainage for all transplants including solitary pancreas transplantation. This shift to enteric drainage has occurred as a result of the significant complications associated with bladder-drained pancreas transplants. These include recurrent urinary tract infections, hematuria, chemical urethritis, severe bicarbonate wasting, and dehydration. Approximately 25% of individuals who receive bladder-drained pancreas transplants require enteric conversion because of persistent complications,⁴⁸ but an additional percentage endure significant morbidity early after transplant. The major advantage of bladder drainage is the ability to monitor urinary amylase, a decrease in which can be associated with rejection. This can be helpful in solitary pancreas transplants, but is perhaps not as important for simultaneous pancreas–kidney transplants where graft function may be monitored by serum creatinine. Improved immunosuppression and an increased utilization of biopsy to diagnose rejection have led to a decreased reliance on urinary amylase.⁴⁹

Enteric drainage is achieved by creating a side-to-side or end-to-side anastomosis of donor duodenum to recipient jejunum. This may be a loop of jejunum, or a Roux-en-Y configuration may be created. For bladder drainage, a side-to-side anastomosis between the donor duodenum and the bladder is performed. Enteric drainage is always used for pancreas transplants with portal venous drainage because the orientation of the pancreas precludes anastomosis of the duodenum to the bladder.

If a simultaneous kidney–pancreas transplant is performed, the kidney transplant is usually placed in the left iliac fossa. The anastomoses, as with a kidney transplant via a retroperitoneal incision, are typically to the external iliac artery and external iliac vein. The kidney is typically placed in an intraperitoneal location, which increases the potential for torsion of the kidney on its vascular pedicle compared with kidney-alone transplants, which are usually placed in a retroperitoneal location. Some surgeons prefer to raise a retroperitoneal flap to place the kidney retroperitoneally after implantation. Advantages to this approach include improved percutaneous access should biopsy be required and a decreased risk of postbiopsy hemorrhage.

Following revascularization of the pancreas, attention is paid to bleeding from the pancreas, which can be quite brisk. These are controlled with ties or suture ligatures. Since thrombosis is a common complication of pancreas transplantation, anticoagulation in the perioperative period is frequently employed, particularly for solitary pancreas transplantation. Thrombosis is less frequent in simultaneous pancreas–kidney transplantation, where uremic platelet dysfunction is protective. The extent of anticoagulation may range from the intraoperative administration of heparin prior to clamping of vessels, followed up by low-dose heparin infusion and warfarin anticoagulation, to more conservative approaches such as the use of low-dose heparin for a limited interval postoperatively, or the use of aspirin or other antiplatelet agents. Hypercoagulability states may predispose to graft thrombosis in a significant number of individuals, although definitive data are lacking, and anticoagulation is not commonly individualized based on risk.⁵⁰ Whatever the approach, patients should be monitored for bleeding, since as many as 5% of patients experience postoperative hemorrhage requiring reoperation.⁵¹

Following revascularization, serum glucose levels are obtained hourly. It is common for the blood glucose to decline significantly following revascularization, and it is not uncommon for it to fall to normal levels soon after the patient's arrival in the recovery room. At some point intravenous fluids should be converted to dextrose-containing solution in order to prevent hypoglycemia. Pancreas transplant recipients with enteric drainage require only maintenance fluid with consideration of

third-space losses. Simultaneous kidney–pancreas transplant recipients require the additional fluid replacement that would be administered following kidney transplantation alone. Individuals who receive bladder-drained pancreas transplants require replacement of pancreatic exocrine losses, which can be quite profound in the early postoperative period.

Immunosuppression

The immunogenicity of a pancreas transplant is considered to be greater than the majority of solid organ transplants because of the extensive lymphoid component of the gland. In addition, the difficulty in diagnosing rejection compared to other solid organ transplants makes the choice of immunosuppression perhaps more significant for pancreas transplants. Most centers use some form of triple maintenance therapy utilizing a calcineurin inhibitor, an antiproliferative agent, and steroids, although steroid-free regimens are becoming more common. According to data from the Scientific Registry of Transplant Recipients, 92% of kidney–pancreas recipients in 2006 received tacrolimus as maintenance therapy, compared to only 6% who received cyclosporine.³¹ Mycophenolate mofetil is the antiproliferative agent of choice in pancreas transplantation, although the use of sirolimus has increased from virtually nil in 1999 to nearly 16% in 2006. The use of steroids for combined kidney transplantation is also decreasing; whereas in 1999, 97% of kidney–pancreas recipients received steroids as part of initial maintenance immunosuppression, this has decreased to 67% in 2006. This pattern of usage is similar to that employed for solitary pancreas transplantation, either PTA or PAK.

The use of induction therapy to inhibit lymphocyte function is common. Two large randomized multicenter trials utilizing diverse agents such as T-cell–depleting antibody induction (OKT3, ATGAM, and thymoglobulin) and interleukin-2 (IL-2) receptor antibody inhibition (daclizumab and basiliximab) showed a reduction in the incidence of acute rejection but failed to demonstrate a significant effect on patient or graft survival.^{52,53} Despite this modest impact on overall graft outcome, 83% of kidney–pancreas transplant recipients received induction therapy in 2006.³¹ Of these, approximately three quarters received thymoglobulin; the remaining were split between anti-IL-2 receptor and Campath induction therapy. For pancreas after kidney transplants, fewer recipients received induction (78%), with a similar proportion receiving thymoglobulin over anti-IL-2 receptor agents or Campath. The International Pancreas Transplant Registry (IPTR) has demonstrated a lower risk of pancreas graft loss in all categories of pancreas transplantation with the use of tacrolimus, and also demonstrated similar associations with the use of mycophenolate mofetil.³⁶ Consistent with the multicenter trials, IPTR analyses also fail to demonstrate a beneficial effect of induction therapy on patient and graft survival.

Several groups have reported excellent intermediate-term patient and graft outcomes utilizing steroid minimization protocols.^{54–56} These protocols generally employ an induction agent (usually a depleting T-cell antibody or Campath), tacrolimus, and either mycophenolate mofetil or sirolimus. Steroids are given for a maximum of 3 days. These steroid minimization protocols, as in kidney transplantation, aim to avoid the significant short- and long-term side effects associated with corticosteroids. Regimens employing maintenance monotherapy have also been successfully employed, although long-term outcomes are not yet established.⁵⁷

Complications

Thrombosis of the pancreas transplant is the most common cause of graft loss in the early postoperative period. Why pan-

creas transplants are more prone to thrombosis than other solid organ transplants is uncertain. The most likely mechanism is that ischemia-reperfusion injury in the pancreas, characterized by the release of cytokines and activation of pancreatic enzymes, leads to accelerated injury and a procoagulant state. Diabetic patients have impaired fibrinolysis and are therefore relatively hypercoagulable. The relatively low venous flow through the portal vein, which leads to diminished flow velocity, may be contributory. Thrombosis is more common in solitary pancreas transplantation than in SPK, probably due to the absence of uremic platelet dysfunction present in SPK recipients. The risk of thrombosis has been associated with donor factors such as older patient age, BMI, and cerebrovascular cause of death.^{35,58}

Pancreas transplant thrombosis is usually heralded by a sudden rise in blood glucose in a pancreas that was previously functioning. Confirmation of the diagnosis is usually obtained with duplex ultrasound. Although anecdotal reports have described successful surgical and angiographic thrombectomy or thrombolysis in restoring flow to the pancreas,^{59,60} the usual treatment is removal of the infarcted pancreas. While this usually occurs immediately after diagnosis, some centers opt to relist the patient urgently and wait until another pancreas transplant becomes available. Depending on the waiting time for another pancreas, the added morbidity of delaying the graft pancreatectomy is usually not significant. Because of the high risk of thrombosis, anticoagulation is frequently employed. It is likely due to these efforts and improvements in immunosuppression that the thrombosis rate has decreased to less than 5% for simultaneous pancreas–kidney transplants and to less than 10% for isolated pancreas transplants.

Bleeding is another frequent cause for reoperation in the early postoperative period. Because of the large number of vessels that enter and exit the pancreas, bleeding following reperfusion is not unusual. While readily controllable, it is not uncommon for bleeding points to emerge later in the procedure, and postoperatively. This can be minimized by meticulous attention to ligating vascular structures during pancreas procurement. The use of anticoagulation in the perioperative period, as described earlier, adds to the bleeding risk. Pancreas transplant recipients are monitored carefully in the early postoperative period for signs and symptoms of intra-abdominal hemorrhage.

The other major early complication is leak from the donor duodenum. Duodenal leaks occur in approximately 10% of cases, usually 1 to 2 weeks after the transplant.⁶¹ A leak may present as fever, abdominal pain, leukocytosis, lower abdominal tenderness, and persistent ileus. The diagnosis may be supported by the finding of a focal fluid collection near the head of the pancreas on CT scanning or ultrasound. Alternatively, diffuse peritonitis may reflect disseminated contamination. For bladder-drained pancreas transplants, the diagnosis may be made by cystography.

The management of a suspected duodenal leak is operative. Peripancreatic sepsis or abscess can occur in the absence of a frank duodenal leak. This is caused by the growth of organisms transmitted into the peritoneal cavity during performance of the duodenal anastomosis. The peritoneum should be lavaged and all necrotic debris removed and débrided. If a leak is present, it is usually at the stapled end of the duodenum rather than at the anastomosis. The likelihood of success for repair of a duodenal leak depends on the viability of the duodenum at the point of the leak, the patient's overall hemodynamic stability, and the degree of surrounding inflammation. Usually one attempt at repair is made, but failure may necessitate removal of the pancreas in order to control life-threatening sepsis. Some surgeons have adopted a practice of managing leaks from duodenal enteric anastomoses by conversion to bladder drainage. This minimizes the risk of recurrent contamination of the peritoneal cavity with enteric contents and allows for Foley catheter decompression of the duodenum, but

has the morbidity associated with bladder drainage. Occasionally a fluid collection or leak that presents late can be treated with percutaneous CT-guided drainage.⁶² In addition, drainage of infection without primary repair of the duodenal leak has been successfully employed in situations where inflammation is so profound that the leak could not be primarily repaired. However, the morbidity associated with these duodenal fistulas dictates that these options be employed only when definitive repair is not possible.

In contrast to renal transplantation, the complications of pancreas transplantation can be severe and life threatening if not properly managed. Even in the most experienced centers, occasional patients who suffer extended intensive care unit stays and even death are not unusual. This is a consequence of both the tenuous medical status of longstanding diabetics and the substantial morbidity of pancreas transplant complications. Therefore, given the limited survival benefit of pancreas transplantation, particularly compared with kidney transplantation, patients should be counseled frankly about the potential magnitude of these complications so that they have a realistic expectation of outcomes. Even with honest discussion and informed consent, most individuals will elect pancreas transplantation, and many will pursue multiple pancreas transplants even with a history of significant complications from previous pancreas transplants.

Diagnosis and Treatment of Rejection

The timely and accurate diagnosis of pancreas transplant rejection is one of the most important and challenging aspects of posttransplant management. As noninvasive means of diagnosing rejection are neither sensitive nor specific, the diagnosis of rejection is best made with the histologic examination of a pancreatic biopsy specimen.⁶³ The pancreas graft in SPK transplants may be monitored by following the serum creatinine, as the concordance rate for rejection between kidney and pancreas grafts is believed to be high.^{64,65} Improvements in the outcome of solitary pancreas transplants are largely attributable to not only improvements in the overall quality of immunosuppression, but also the ability to more accurately diagnose and treat pancreas rejection.

The technique of pancreas transplant biopsy has evolved over the years. In the era of bladder-drained pancreas transplants, cystoscopic biopsy of both the pancreas and transplant duodenum was common.⁶⁶ As more enteric-drained pancreas transplants have been performed, a greater reliance on percutaneous biopsy has developed, using either ultrasound or CT-guided techniques.⁶⁷ Laparoscopic-assisted or open pancreas biopsy may be utilized for patients whose pancreas transplant may not be accessible to percutaneous approaches, although the need for operative biopsy is decreasing as the percutaneous procedure has become more routine.⁶⁸ The indications for pancreatic biopsy include hyperamylasemia, hyperlipasemia, hyperglycemia, or unexplained pain in the vicinity of the pancreas transplant. The differential diagnosis includes pancreatitis, cytomegalovirus infection, toxicity from calcineurin inhibitors, and, in the early postoperative period, peripancreatic infection. The histologic grading system developed at the University of Maryland for determining rejection grade in pancreas biopsies is generally used (Table 39.1).⁶⁹ Indeterminate rejection may be treated with increases in calcineurin inhibitor dose or pulse corticosteroids. More substantial rejection is generally treated with depleting antilymphocyte antibody therapy, either OKT3 or Thymoglobulin.

As long-term survival of pancreas transplants becomes more commonplace, chronic rejection is emerging as an important problem.⁷⁰ Chronic rejection is histologically characterized as expansion of fibrous septa within the pancreatic parenchyma. This may progress to lobular atrophy or loss of both acini and β cells. Although there are parallels to chronic allograft nephropathy, whether chronic calcineurin inhibitor toxicity contributes to chronic pancreas rejection is unknown.

Recurrent Autoimmunity

Selective β -cell destruction in pancreas transplants may occur in a pattern similar to the insulinitis seen in type 1 diabetes. This pattern is histologically distinct from cellular rejection. Although recurrent autoimmunity has been documented in both immunosuppressed pancreas transplant recipients and nonimmunosuppressed living donor recipients from identical twin siblings, well-documented case series have been infrequent. A variety of

TABLE 39.1

CLASSIFICATION

PROPOSED BANFF CLASSIFICATION FOR GRADING PANCREAS ALLOGRAFT ACUTE CELLULAR REJECTION

■ GRADE	■ SEVERITY	■ FINDINGS
	Normal	Absent inflammation or inactive septal, mononuclear inflammation not involving ducts, veins, arteries, or acini. There is no graft sclerosis. The fibrous component is limited to normal septa and its amount is proportional to the size of the enclosed structures (ducts and vessels). The acinar parenchyma shows no signs of atrophy or injury.
	Indeterminate	Septal inflammation that appears active but the overall features do not fulfill the criteria for mild cell-mediated acute rejection
I	Mild	(a) Active septal inflammation (activated, blastic lymphocytes \pm eosinophils) involving septal structures: venulitis (subendothelial accumulation of inflammatory cells and endothelial damage in septal veins), ductitis (epithelial inflammation and damage of ducts); neural/perineural inflammation and/or (b) focal acinar inflammation: no more than two inflammatory foci per lobule with absent or minimal acinar cell injury
II	Moderate	(a) Multifocal (but not confluent or diffuse) acinar inflammation (three or more foci per lobule) with spotty (individual) acinar cell injury and drop-out and/or (b) minimal intimal arteritis
III	Severe	(a) Diffuse (widespread, extensive) acinar inflammation with focal or diffuse multicellular/confluent acinar cell necrosis and/or (b) moderate or severe intimal arteritis and/or (c) transmural inflammation: necrotizing arteritis

associations have been suggested with autoantibodies to glutamic acid decarboxylase (GAD-65) and islet cells (IA-2), but patterns of autoantibody expression have not proven reliable enough to establish their etiologic relevance or prognostic value.

Posttransplant Viral Infections. The higher level of immunosuppression given to pancreas transplant recipients compared with kidney transplant recipients, particularly with respect to lymphocyte-depleting induction therapy, places pancreas transplant recipients at risk for conditions known to be influenced by overall immunosuppressive exposure. While rates of cytomegalovirus (CMV) infection are generally higher than for kidney recipients, especially when the donor is known to carry the virus, the use of intravenous and oral ganciclovir over the past decade has reduced the incidence of significant CMV-associated disease.^{71,72} The incidence of CMV disease may also be lower in those recipients receiving steroid-free immunosuppression.⁷² Data are mixed with respect to the incidence of polyoma-associated, or BK, nephropathy, with some analyses suggesting a higher rate and others an equivalent incidence in SPK recipients compared with kidney-alone recipients.^{73,74} As with kidney-alone recipients, those SPK recipients with BK nephropathy have inferior kidney graft survival. Post-transplant lymphoproliferative disorder (PTLD), often associated with Epstein-Barr virus (EBV) infection, has a 5-year incidence of approximately 2%, which is similar to kidney recipients.⁷⁵ However, pancreas recipients with PTLD may have a worse prognosis than other abdominal organ transplant recipients with PTLD.

Results of Kidney–Pancreas Transplantation

There were 6,832 recipients of SPK transplants alive with functioning grafts at the end of 2005.³¹ Current kidney graft survival at 1 and 5 years following SPK transplantation is 93% and 78%, respectively. African-Americans have somewhat poorer five-year graft survival (71%) than whites (79%). Kidneys from older donors have the poorest graft survival; 5-year graft survival from donors older than 50 is 68% compared with approximately 80% from donors aged 11 to 34. As opposed to previous decades, 5-year kidney graft survival is not associated with HLA matching.

- 5 Pancreas graft survival at 1 and 5 years following SPK transplantation is 86% and 73%, respectively (Fig. 39.6).

FIGURE 39.6. Pancreas graft survival for U.S. transplants. Cohorts are transplants performed during 2005 for 3-month and 1-year survival; 2003 for 3-year survival; and 2001 for 5-year survival. (Data from Scientific Registry of Transplant Recipients. 2007 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2008.)

FIGURE 39.7. Patient survival for U.S. pancreas transplant recipients. Cohorts are transplants performed during 2005 for 3-month and 1-year survival; 2003 for 3-year survival; and 2001 for 5-year survival. (Data from Scientific Registry of Transplant Recipients. 2007 Annual Report. Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2008.)

Worse 5-year graft survival is seen in African-American (68%) recipients compared with whites (73%). Five-year graft survival from donors over age 50 years (66%) is significantly lower than those from donors under 35 years (74%), including those under 10 years of age. Recipients with a previous transplant (kidney, pancreas, or both) have worse pancreas graft survival. As with kidney survival, there is no difference in 5-year pancreas graft survival with increasing levels of HLA mismatch.

Registry analyses demonstrate a mortality benefit of SPK transplantation compared with dialysis⁷⁶ or kidney transplantation alone.⁷⁷ Patient survival at 1 year and 5 years following SPK transplantation is 95% and 85%, respectively (Fig. 39.7). Race, ethnicity, sex, and transplant center volume are not associated with decreased patient survival at 5 years, and patient survival has improved since 1995 but not appreciably in the past 5 years. Death rates for recipients continue to be lower than the corresponding death rates for candidates on the SPK waiting list. Older (ages 50 to 64) and African-American recipients tend to have higher death rates in the first year following transplantation.

Results of Solitary Pancreas Transplantation

The 1-year pancreas graft survival for recipients of a PAK transplant has improved in the last 5 years, although the 1-year unadjusted graft success decreased from 82% for PAK transplants performed in 2001 to 78% for PAK transplants performed in 2005.³² The graft survival for PAK at 3 years and 5 years is currently 64% and 60%, respectively. Patient survival for PAK recipients is excellent, 98% and 83% at 1 and 5 years, respectively.

One-year pancreas graft survival for PTA has improved in the last 5 years to 85% for transplants performed in 2005. The unadjusted graft survival for PTA at 3 and 5 years is 60% and 54%, respectively. Graft survival rates for PTA are better than PAK early but the rate of graft failure in the long term is greater for PTA than for PAK. Patient survival rates for PTA recipients are 98% at 1 year and 87% at 5 years.

Whether pancreas transplantation positively impacts patient mortality is controversial. One study reported that

registrants on the waiting lists for PAK and PTA had better survival rates than recipients who underwent these procedures.⁷⁶ Subsequently, another group, using a similar cohort but different analytical methods, reported better survival rates for recipients of solitary pancreas transplantation than registrants on the waiting list.⁷⁸ These discrepancies are in part related to the differing methodologies used in the two studies with respect to deaths among those removed from the waiting list and to variability in the year-to-year death rates on the waiting list. In contrast, both studies demonstrated a conclusive benefit for SPK recipients compared with remaining on the waiting list, which illustrates the importance of restoration of kidney function in this population, as with kidney-alone transplant. While opinions on the specific benefit of the pancreas transplant differ in light of the differing conclusions of these two studies, together the studies indicate that any survival benefit conferred by the pancreas transplant is likely to be modest.

Effect of Pancreas Transplantation on Secondary Complications of Diabetes Mellitus

There are data that clearly demonstrate the impact of pancreas transplantation on the course of secondary complications of diabetes. This could to some extent be predicted from the results of the DCCT, in that pancreas transplantation leads to a complete normalization of blood glucose and glycosylated hemoglobin levels that are vastly superior to those achievable by intensive insulin therapy. Therefore, it should not be surprising that pancreas transplantation has an impact on diabetic complications.

For example, while type 1 diabetic recipients of kidney transplants alone show typical findings of diabetic nephropathy following transplantation, SPK transplantation prevents the development of recurrent diabetic nephropathy.⁷⁹ In addition, native diabetic nephropathy has been demonstrated to reverse 10 years following successful isolated pancreas transplantation.⁸⁰ These reports demonstrate convincingly that pancreas transplantation has a significant impact on diabetic nephropathy. Effects on diabetic neuropathy have also been documented using nerve conduction studies, which are significantly improved following pancreas transplantation.⁸¹ Small corneal nerve fiber regeneration can be detected.⁸² Furthermore, clinical progression of diabetic neuropathy is significantly diminished compared to nontransplanted controls. However, no study has been able to demonstrate clinical improvement in existing diabetic neuropathy following transplantation. There is also an impact on autonomic neuropathy, with clinical improvement in epinephrine responses to hypoglycemia.⁸³ While the DCCT demonstrated a relationship between glycemic exposure and retinopathy, the effect of pancreas transplantation on retinopathy is only modest. While stabilization of moderate retinopathy has been demonstrated, long-term graft function (>3 years) is required.^{84,85} Many pancreas transplant candidates have advanced retinopathy, and an effect has not been demonstrated in these individuals. Early acceleration of retinopathy, a phenomenon that has been noted with other methods of improving glycemic control, can occur in the first 6 to 12 months following transplant. Despite the findings of the DCCT trial, an assessment of the impact of pancreas transplantation on the progression of atherosclerosis is lacking a definitive large-scale study. Smaller single-center studies are mixed, with some centers demonstrating a positive impact on peripheral vascular occlusive disease, and others demonstrating a worsening of disease.^{86,87}

Regardless of the magnitude of objectively demonstrable benefits of pancreas transplantation, most recipients enjoy a dramatic improvement in quality of life.^{65,88,89} While many diabetics can adapt quite well to the dramatic glucose fluctua-

tions and the associated morbidity of diabetes, the freedom from insulin and the avoidance of hyper- and hypoglycemia offered by a functioning pancreas transplant is a primary motivator for many recipients. The fervor with which many candidates pursue pancreas transplantation, especially retransplantation, is an indication of the enormous benefit on quality of life for these individuals.

ISLET TRANSPLANTATION

Overview

The notion that insulin-producing β cells could be physically separated from the pancreas and transplanted for the treatment of diabetes has long been recognized. Islet transplantation, as a cellular transplant, has significant potential advantages over whole-organ pancreas transplantation. Islet transplantation does not require an operative procedure.⁹⁰ In addition, the potential ability to preserve islets without impairment of graft function opens up possibilities with regard to distribution, allocation, transportation, and preparation of the islet recipient. Pretreatment of the graft to reduce immunogenicity or enhance survival and function is also possible.⁹¹ Recipients of successful islet transplants can have glucose metabolism and insulin secretion profiles that are close to normal and maintain metabolic control in a manner equivalent to whole-pancreas transplantation.⁹² Although effects on mortality and progression of diabetic complications are unproven, these benefits are also anticipated. From a long-range perspective, the development of islet transplantation sets some of the procedural, technical, and regulatory groundwork for the eventual establishment of stem cell-derived β -cell transplantation.

History

The development of islet transplantation was historically limited by poor graft survival. The first human islet allograft in a type 1 diabetic was performed in 1974 by the University of Minnesota.⁹³ The first islet autograft for the treatment of chronic pancreatitis was performed at Minnesota in 1977. Despite intense research in islet transplantation over three decades, until 2000, clinical islet transplantation met with minimal success.⁹⁴ While the transplanted islets were capable of physiologic function, as evidenced by the 66% rate of insulin independence at 1 year in the 163 recipients of islet autografts from 1974 to 1995, even these recipients had significantly reduced functional β -secretory reserve.⁹⁵ Alloimmunity to the islets presented an even greater hurdle; in the 96 islet allograft recipients with type 1 diabetes from 1990 to 1994, C-peptide production and insulin independence at 1 year were 25% and 7%, respectively.⁹⁴ Of the 270 recipients until 1999, only 6 had achieved insulin independence for greater than 2 years.

The dramatic improvement in islet transplant outcome reported by the Edmonton group in 2000 stimulated an increase in islet transplant activity.⁹⁶ Several important refinements in islet isolation and immunosuppression have largely been credited for the improvement in outcomes, including careful attention to pancreas procurement, minimization of cold ischemia time of the pancreas prior to isolation, avoidance of xenoproteins in the islet isolation process, and avoidance of steroids in the immunosuppressive regimen. Furthermore, the use of sequential infusions to achieve insulin independence has been critical to success for many centers. The enthusiasm that accompanied this recent success has been tempered recently by the inability for many new centers to replicate the success of more established centers,⁹⁷ the disappointing long-term survival of the transplants,⁹⁸ and the costs

FIGURE 39.8. Isolated, purified human islets. Islets are stained red with diphenylthiocarbazone. (Adapted from Robertson PR. Islet transplantation as a treatment for diabetes: a work in progress. *N Engl J Med* 2004;350:694–705.)

associated with islet transplants, which are not routinely reimbursed by insurers.⁹⁹ As a result, the volume of islet transplants has contracted in the past few years.¹⁰⁰

Islet Isolation

The precise separation of the islets from the other tissues of the pancreas (exocrine cells, lymphatics, vascular structures) is perhaps the most important determinant of successful islet transplantation (Fig. 39.8). One of the limitations of islet isolation is the difficulty in getting a large number of high-quality islets, and consistent success in islet isolation is a combination of science, art, and experience. Although a variety of methods have been utilized, most currently employ some modification of the semiautomated method described by Ricordi in 1988.¹⁰¹ This method combines mechanical distention with enzymatic digestion of the pancreas. After cleaning the pancreas of surrounding fat, the pancreatic duct is cannulated with an angiocatheter and the pancreas is distended and loaded with warm collagenase solution, which digests the pancreas.¹⁰² The pancreas is then placed into a sterile chamber, which also contains a number of stainless steel or glass spheres. Additional collagenase solution is added, and the chamber is attached to a shaking apparatus or agitated by hand. The collagenase solution is recirculated and kept at 37°C as the chamber is agitated. Agitation of the chamber allows the spheres to continue to disrupt the structural integrity of the pancreas as it digests. Following digestion, the separation of islets from nonislet tissue is performed via density gradient centrifugation. After suspension in culture media, islets are counted and assessed for sterility, purity, viability, and functional capacity. As islet isolation in the United States is regulated by the U.S. Food and Drug Administration, stringent product release criteria are in place to ensure the quality of the transplanted islets. The percentage of islet isolations that result in a transplantable preparation varies widely among centers, between 25% and 70%, and depends on both donor selection practices and the experience and expertise of the particular center.

Patient Selection

Candidates for islet transplantation are selected in a similar manner as for whole-organ pancreas transplantation. Islet transplantation is currently limited to adult type 1 diabetics with progressive diabetic complications who have failed inten-

sive insulin therapy. Because islet transplantation remains experimental therapy with limited availability, the procedure is offered only to ideal candidates with minimal medical conditions other than diabetes. Most centers require evaluation and/or a period of treatment by an experienced endocrinologist specializing in diabetes. Candidates with coronary artery disease; chronic infections, including hepatitis B and C; or a prior solid organ transplant are excluded. Nonuremic candidates must be free of renal insufficiency, due to concerns about aggravation of nephropathy by calcineurin inhibitors. Since efficacy of the islet transplant appears to be related to the number of islets transplanted per kilogram of recipient body weight, only lean (<70 kg or BMI <28) recipients are selected. Although most islet transplants are currently performed in nonuremic diabetics, islet transplants either concurrent with or following kidney transplantation are also performed.^{103,104}

Donor Selection, Procurement, and Preservation

Donor selection for islet isolation differs from that for whole-pancreas transplantation in several respects. While the ideal donor for islet isolation is still young and healthy, the age and weight criteria are less stringent than for whole-pancreas transplantation. Donors older than age 50, donors on vasopressors, and especially obese donors are all perfectly suitable for islet isolation. Since the ideal pancreas is easily distensible and digestible, fatty pancreata are felt to be especially suitable, whereas fibrotic pancreata are not. As previously mentioned, pancreata from older and obese donors (which are infrequently used for whole pancreas) are preferentially allocated for islet transplantation rather than for regional and national sharing for whole-pancreas transplantation.³³

The pancreas is procured in a manner similar to whole-pancreas transplantation. However, less attention to preservation of vascular structures is required. Attention is paid to surface cooling following flushing of preservation solution, and avoidance of pancreatic injury. A number of reports have highlighted the importance of a dedicated team trained in pancreas procurement in the success of islet isolation.^{105,106} Expanded use of the two-layer technique of pancreas preservation, using both standard preservation solution (University of Wisconsin solution or HTK) and oxygenated perfluorocarbon solution, has resulted in increased islet yields.^{107–109} The two-layer technique also permits the successful use for islet transplantation of pancreata subjected to prolonged cold ischemia as long as 18 hours. Success with pancreata from DCDs has been reported.¹¹⁰

Transplant Techniques

The portal circulation of the liver is currently the preferred site for islet transplantation (Fig. 39.9).¹¹¹ This can be performed by a minilaparotomy, with infusion of the islets into a peripheral mesenteric vein. However, most centers utilize interventional radiology techniques, avoiding both a surgical incision and general anesthesia. Percutaneous transhepatic portal vein catheterization is done under ultrasound and fluoroscopic guidance, with usually a small-gauge (4-French) catheter. The islets are infused into the portal vein through the catheter by either gravity from an infusion bag or by hand injection, and the islets lodge in the hepatic parenchyma. Portal vein pressure is monitored intermittently throughout the procedure. Following infusion of the islets, hemostasis is usually achieved using a combination of coils and Gelfoam. Recipients receive heparin in the islet preparation, systemically during the procedure, and in the perioperative period as prophylaxis against portal vein thrombosis, a now rare but serious complication.

FIGURE 39.9. Islet transplantation. The pancreas is procured as a whole organ from the donor. The islets are isolated from the pancreas and are purified and infused into a cannula placed in a branch of the recipient's portal vein.

Perioperative Care

Although islet transplantation is in theory an outpatient procedure, it is not uncommon for recipients to receive a few days of inpatient care for monitoring purposes. Immediately following the islet transplant, patients are maintained on bed rest for a short interval and monitored for bleeding. Liver function tests are monitored, and a liver ultrasound is frequently done to assess portal venous flow and to check for hematoma. It has been demonstrated that intensive glycemic control with insulin in the immediate posttransplant period is beneficial for islet function.¹¹² Hence, many centers will give insulin postoperatively to keep the serum glucose tightly controlled, in order to “rest” the islets. Additional adjuncts to prevent nonspecific inflammation may include antioxidants such as vitamin E, antibodies against tumor necrosis factor- α , pentoxifylline, and others.

Immunosuppression

Current thinking focuses on the importance of the elimination of steroids from the immunosuppressive regimen, which typically uses basiliximab induction, and maintenance therapy with low-dose tacrolimus and sirolimus. Regimens employing mycophenolate mofetil and cyclosporine are also used, and thymoglobulin is an alternative induction agent. The best results for islet–kidney transplantation are cases where steroids are avoided or eliminated at the time of islet transplantation. Long-term effects of either the islet transplant or steroid elimination on kidney function are not known, and steroid avoidance in kidney transplant recipients is becoming increasingly common.³¹

Metabolic Control

Islet recipients show significant improvement in metabolic function and glycemic reserve. Although hormonal counter-

regulation to hypoglycemia is diminished, actual hypoglycemic events are rare.¹¹³ However, islet recipients have significantly more diminished β -cell reserve than do recipients of whole-pancreas transplants, which may account for their reduced long-term survival.¹¹⁴ Analyses of the impact on diabetic complications and mortality await further experience.

Complications

Morbidity from islet transplantation is substantial but much less than for whole-pancreas transplantation. The most common serious complication is bleeding (1% to 5%). Most cases of bleeding can be managed nonoperatively with adjustments in anticoagulation, though occasionally laparotomy is required. The side effects of immunosuppression, such as hyperlipidemia and mouth ulcers in sirolimus-containing regimens, are much more common and can significantly affect quality of life.¹¹⁵ Renal insufficiency is an uncommon but serious consequence.⁹⁸ Transient elevations of portal venous pressure during islet infusion and elevations of liver function tests following infusion are common and usually well tolerated.^{116,117} Recently, the demonstration of late steatosis has raised concerns about chronic liver disease; to date, this has not occurred.¹¹⁸ Cytomegalovirus infection is rare. Sensitization to alloantigen does occur, although perhaps to a lesser extent than for whole-organ transplants.⁹⁸ Mortality is virtually nil.

Results

- 8 The short-term results of islet transplantation at high-volume centers are approaching that of whole-pancreas transplantation. The most successful centers achieve insulin independence rates of 80% to 90% at 1 year.^{96,119,120} In the Immune Tolerance Network multicenter trial of the Edmonton Protocol, success rates at the most successful centers (Edmonton, Minnesota, and Miami) were significantly higher than at the other

centers.⁹⁷ However, long-term rates of insulin independence are significantly worse than whole-pancreas transplants: in most centers less than 50% of recipients are insulin-free at 3 years, and at the University of Alberta the median insulin-free interval was 15 months.⁹⁸

One of the shortcomings of islet transplantation compared with whole-pancreas transplantation is the inability to reverse diabetes with the islets from one pancreas. Most of the recipients in the modern era have required two or more islet infusions to achieve insulin independence. However, some centers have successfully employed single-donor islet transplantation by utilizing careful donor and recipient selection, usually by transplanting islets from pancreata from large donors into small recipients.^{119,121,122} However, as long-term outcome appears to be related to β -cell mass, which is likely to be lower for single-donor infusions, these recipients may return to insulin or require retransplants earlier.¹²³

The ability to maximize the use of islets and minimize islet requirements and pancreas utilization for an individual recipient is critical if islet transplantation is to compare favorably with whole-pancreas transplantation.

Graft Failure

Graft failure appears to occur earlier than for whole-pancreas transplants. This may be related to a lower initial islet mass or the inability to histologically diagnose and treat islet rejection, since the islets are scattered about the liver parenchyma. Attempts to identify immunologic markers of rejection or recurrent autoimmunity, or metabolic indicators of impending graft failure are not of sufficient predictive value for clinical application.^{124,125} Recipients with prior graft function who have returned to insulin are candidates for retransplantation. In fact, some centers have used transplanted islets from isolations where yields are insufficient for a primary transplant as retransplants, where the islet requirement may be less.

THE FUTURE OF PANCREAS AND ISLET TRANSPLANTATION

Many challenges remain in determining the ideal insulin replacement therapy for type 1 diabetics. While the current allocation system designed to maximize whole-pancreas transplantation ensures the most efficient use of donor pancreata, improvements in the efficiency of islet isolation may require that further refinements be made to allocation policy. Current outcomes support the prioritization of whole-pancreas transplantation over islet transplantation, and sufficient long-term survival reproducible among a larger number of centers may be required before islet transplantation can move further into the mainstream. If this occurs, the reduced morbidity of islet transplantation may mean that a large number of candidates who are not surgical candidates for pancreas transplantation may be islet candidates in the future. Many centers have taken the philosophical step to offer islet transplantation primarily to diabetics who would not otherwise receive immunosuppression (i.e., nonuremic diabetics). This is somewhat in contrast to PTA transplantation, which is offered to only the most exceptional candidates. Taken further, islet transplantation could theoretically be open to a large number of type 1 diabetics who would surely exhaust the limited supply of human donor pancreata. However, the experience gained by the development of islet transplantation would surely apply to technologies not affected by donor supply, such as islet xenografts or engineered β cells, which could have a profound impact on the devastating effects of diabetes on the public health worldwide.

CHAPTER 40 ■ HEAD AND NECK

MATTHEW C. MILLER, JEFFREY S. MOYER, AND THEODOROS N. TEKNOS

KEY POINTS

- 1 Tobacco and alcohol are the best-recognized risk factors for head and neck cancers. Their effects are synergistic.
- 2 No head and neck examination is complete until all mucosal surfaces of the upper aerodigestive tract have been visualized.
- 3 Early recognition of and preparation for a potentially difficult airway may prevent it from becoming an emergency airway.
- 4 The most common neoplasm in the head and neck is squamous cell carcinoma.
- 5 Cystic neck masses in adults are metastatic oropharyngeal carcinoma until proven otherwise.
- 6 In any smoker aged 35 or older with hoarseness, a neck mass, or mucosal abnormality, carcinoma must be ruled out.

The head and neck is a complex and intricate region of the body, and surgical management of head and neck diseases is both challenging and rewarding. A wide variety of benign and malignant processes are encountered by the head and neck surgeon, and a comprehensive review of this material is well beyond the scope of this chapter. However, head and neck complaints are relatively common and it behooves the surgeon to familiarize himself or herself with the processes. With that in mind, the following chapter is designed to introduce the reader to head and neck diseases, provide a framework for diagnostic evaluation, and discuss the treatment strategies commonly employed.

EVALUATING THE PATIENT WITH A HEAD AND NECK COMPLAINT

Patient Presentation and History

Though a few patients will be referred to the head and neck surgeon for incidentally discovered abnormalities, the vast majority of patients will present with a specific head and neck complaint. As with any medical discipline, concise history taking begins with questions aimed at determining the onset, severity, location, and quality of the presenting symptom along with any exacerbating or alleviating factors. Once this is completed, a head and neck review of systems should be obtained. Pertinent positives and negatives in this category will help to narrow the differential diagnosis and might point to the presence of an underlying malignancy. Table 40.1 lists common signs and symptoms that are associated with head and neck cancers. When any of these are present—particularly in the context of tobacco use or other risk factors (Table 40.2)—malignancy must be strongly considered.

The social history is of vital importance in evaluating patients with head and neck complaints. Tobacco and alcohol use history must be specific and detailed. Tobacco users have up to 25 times the risk of head and neck squamous cell carcinoma when compared to nonusers. These carcinogenic effects are increased synergistically among heavy consumers of alcohol.^{1,2} Type, amount, and duration of use should be documented as well as any previous efforts to quit (including methods used). Any significant secondhand smoke exposure should also be documented. Passive smoking either at home or at work is often overlooked during the history, but its role in the pathogenesis of many head and neck cancers is becoming increasingly evident.³

Human papillomavirus (HPV) infection is now widely recognized as a risk factor for oropharyngeal cancer. HPV is transmitted sexually, and the risk of oropharyngeal cancers has been strongly correlated to the lifetime number of sexual partners.⁴ Consequently, the sexual history has become an important component of the overall assessment if carcinoma is suspected—particularly in the absence of other risk factors.

Additional medical, surgical, family, and occupational history should also be documented at this point. While these items may or may not have direct implications to the presenting problem, they may be critical to the overall patient evaluation and therapeutic decision-making process.

Physical Examination

Once an appropriate patient history has been obtained, a comprehensive head and neck examination should be undertaken. Many of the techniques and equipment used in the head and neck exam are specialized and may be unfamiliar to some practitioners. However, the examiner must become facile with them to perform a complete and appropriate patient evaluation. At a minimum, physicians treating head and neck disorders should have at their disposal and be comfortable using a stethoscope, a pneumatic otoscope, an assortment of angled mirrors, and nasal specula. A headlight or head mirror should be worn. This allows for the use of both hands during examination and provides superior visualization as compared to the omnipresent “single hand and flashlight” technique. Though most of the upper aerodigestive tract is visible by direct or indirect (mirror) examination, portions of the nasal cavity, nasopharynx, hypopharynx, and larynx are often difficult to assess. The flexible fiberoptic nasopharyngolaryngoscope (NPL scope, or NPL) has become an indispensable tool for this purpose.

Physical examination need not follow a strict sequence per se. However, the entire surface of the head, neck, and upper aerodigestive tract must be evaluated. It behooves the examiner to develop his or her own systematic approach to prevent inadvertent omissions. It is the authors' practice to progress sequentially from the least to the most invasive portions of the exam. This allows for a gradual building of rapport and trust during what can for many patients be a sensitive exam and an invasion of personal space. It generally begins by visually inspecting the patient's face, neck, and scalp—paying attention to any asymmetry or irregularity of natural contours, cutaneous lesions, neuromuscular deficits, scars, or other stigmata of previous surgery and/or radiation therapy. Palpation of the neck ensues,

TABLE 40.1

DIAGNOSIS PROGRESSIVE SIGNS AND SYMPTOMS THAT MAY INDICATE A HEAD AND NECK CANCER

Odynophagia
 Dysphagia
 Weight loss
 Loose dentition
 Oral fetor
 Trismus
 Otagia
 Neck mass
 Serous otitis media
 Nasal obstruction
 Epistaxis
 Facial pain
 Cranial neuropathies
 Secondary infections
 Aspiration
 Fistulization
 Hemorrhage
 Voice changes
 Stridor
 Airway obstruction

TABLE 40.2**ETIOLOGY**

SELECTED RISK FACTORS FOR HEAD AND NECK MALIGNANCY

SKIN CANCER

Ultraviolet and ionizing radiation
 Neoprene inorganic arsenics
 Burns
 Riboflavin deficiencies

NOSE AND PARANASAL SINUS CARCINOMA

Wood dust
 Leather manufacturing
 Nickel refining
 Radium dial painting
 Thorotrast and mustard gas

NASOPHARYNGEAL CARCINOMA

Nitrosamine
 Salted fish
 Epstein-Barr virus
 Vitamin deficiency
 Chinese heritage
 Eskimo heritage

ORAL CARCINOMA

Betel nut chewing
 Snuff
 Tobacco chewing
 Reverse smoking
 Syphilis
 Vitamin B and riboflavin deficiencies
 Chronic irritation

LARYNGEAL AND HYPOPHARYNGEAL CARCINOMA

Asbestos
 Coke oven exposure
 Wood dust
 Riboflavin deficiency
 Gastroesophageal reflux disease
 Fanconi anemia

SALIVARY GLAND CARCINOMAS

Radiation exposure
 Eskimo heritage

THYROID CARCINOMA

Radiation exposure
 Iodine deficiency
 Genetic inheritance

TABLE 40.3 **DIAGNOSIS**

MOST COMMON PRIMARY SITES IN PATIENTS PRESENTING WITH NECK MASSES

■ NODAL LEVEL	■ PRIMARY SITE
I	Oral cavity
II	Oropharynx Nasopharynx Supraglottic larynx
III	Hypopharynx Larynx
IV	Thyroid Hypopharynx Larynx Subclavicular sites
V	Scalp Nasopharynx

with attention to the salivary glands, cervical lymph nodes, thyroid, trachea, and laryngeal cartilages. Auscultation of the neck and chest should also be accomplished. This is followed by formal cranial nerve assessment and pneumatic otoscopy. The remainder focuses on the mucosa-covered surfaces and should include a speculum exam of the nasal cavity, inspection of the oral cavity using a tongue blade in each hand to manipulate the soft tissues, bimanual palpation of the oral cavity and oropharynx, and indirect visualization of the nasopharynx, hypopharynx, and larynx with either the mirror or the NPL.

Documentation of the exam should include detailed descriptions and diagrammatic representations of any abnormality. Size, location, extent, and character should be included for any suspected neoplasm. When cervical adenopathy is present, the number, size, and anatomic level (Fig. 40.1) of the involved lymph nodes should be reported. The pattern of nodal spread from head and neck cancers is relatively predictable. In the presence of a neck mass, the nodal level involved may help to identify an occult primary tumor. Conversely, finding an unusual drainage pattern from a known primary tumor can alert the examiner to the presence of a second primary lesion (Table 40.3).⁵

The following sections review many of the conditions seen in a surgical head and neck practice. Coupled with the information garnered through the history and physical exam, it will provide a framework for generating and ultimately narrowing the differential diagnosis.

AIRWAY MANAGEMENT

Many conditions affecting the head and neck can result in upper airway obstruction. Obstruction may be chronic, as in the case of some neoplasms, or it may be acute, as in the case of hemorrhage or trauma. In either case, it is crucial that the surgeon be familiar with the techniques involved in securing an impaired airway.

3 *Management of the difficult airway begins with early recognition.* The historical and clinical elements listed in Table 40.4 may be associated with difficult intubation and/or airway obstruction. If attention is paid to these signs and symptoms, potentially hazardous situations may be anticipated and addressed in a controlled fashion before a difficult airway becomes an emergency airway. Orotracheal intubation remains the preferred means of accomplishing this goal. However, various conditions

TABLE 40.4 **DIAGNOSIS**

CLINICAL AND HISTORICAL ELEMENTS THAT MAY BE ASSOCIATED WITH DIFFICULT INTUBATION

Head and Neck Tumors (Both current and previously treated)
Trismus
Stridor
“Hot-potato” voice
Obesity
Sleep apnea
Micrognathia
Retrognathia
Macroglossia
Angioedema
Prior thyroid surgery
Prior orthognathic surgery
Facial fractures

render the airway “difficult” and may preclude successful intubation. As a consequence, surgical intervention may become necessary.

Tracheostomy is the gold standard surgical airway. Elective tracheostomy is typically performed in a controlled setting (i.e., in the operating room). In an intubated patient, this procedure is undertaken under general anesthesia. If intubation cannot safely be performed, local anesthesia is used and tracheostomy is carried out on the awake, spontaneously breathing patient. Despite the anxiety and discomfort that may accompany this procedure, anxiolytics and sedatives must be used with caution. Continuous and detailed communication with the anesthesiologist is vital in the perioperative period and throughout the case. Figure 40.2 outlines the primary steps involved in elective tracheostomy.

In emergency situations, the procedure is identical with one significant distinction: Whereas elective tracheostomy uses a horizontal incision, emergent or urgent airway situations call for one that is vertically oriented along the midline of the neck (Fig. 40.2A). This reduces the risk of inadvertent injury to the anterior jugular veins and the associated increase in difficulty and time needed to secure the airway.

An alternative to the emergent tracheostomy is the cricothyrotomy. Cricothyrotomy has the advantage of being technically easier and faster to perform than tracheostomy. It is a means of rapidly securing the airway when the patient is in danger of imminent death because of mechanical respiratory obstruction. However, cricothyrotomy has the disadvantage of being a temporary solution. Instrumentation of the cricothyroid membrane may result in injury to the vocal folds as well as subglottic stenosis.⁶ Consequently, the smallest endotracheal or tracheostomy tube that permits adequate ventilation should be used. Once the patient is stably ventilated, this should immediately be converted to a formal tracheostomy to prevent long-term damage to the larynx and proximal trachea.

NONNEOPLASTIC DISORDERS

Sialadenitis and Sialolithiasis

The three pairs of major salivary glands include the parotid, submandibular, and sublingual glands. In addition, there are hundreds of minor salivary glands situated diffusely throughout the oral cavity, pharynx, and larynx. A wide variety of nonneoplastic conditions can eventuate in swelling of either

FIGURE 40.2. Tracheostomy. **A:** The incision for an elective tracheostomy is typically placed on a horizontal axis, approximately 2 finger breadths above the sternal notch. A vertical incision allows for less bleeding when the procedure must be performed emergently. **B:** The strap muscles are separated in the midline. The thyroid isthmus may bulge into the wound (C), necessitating inferior retraction or division (D). **E:** After the second tracheal ring is cleaned, an inferiorly based flap (i.e., Björk flap) is developed in the tracheal wall and sutured to the skin. This allows for easy access to the trachea while the tract is maturing.

the major or minor salivary glands—though they are most often observed in the paired major glands.⁷ Table 40.5 lists several commonly encountered etiologic agents. Among these, infectious causes are most frequent. Mumps and other viruses may lead to diffuse bilateral swelling of the parotid and, to a lesser extent, the sublingual and submandibular glands.⁷ Treatment is generally supportive.

Acute suppurative sialadenitis presents in a more fulminant fashion, with sudden onset of salivary gland pain and swelling. Acute sialadenitis is most often seen in the context of dehydration and xerostomia. The condition is commonly seen in the postoperative setting, particularly among patients undergoing gastrointestinal operations.⁷ When compared to viral etiologies, bacterial sialadenitis is more often unilateral and is associated with a tense and tender gland. Purulent material may be expressed from the Wharton or Stensen duct during bimanual palpation. This material, when cultured, typically yields *Staphylococcus aureus*. However, other aerobic and anaerobic organisms have also been implicated.⁸ Management is aimed at improving salivary flow through aggressive hydration, massage, warm compresses, and sialogogues such as sour candy and lemons. Antibiotic therapy should be initiated and should be broad enough to cover *S. aureus* and gram-positive aerobes. Rarely, parotitis may progress to an intraparotid abscess. This should be suspected in patients who are not responding to conservative therapy after 48 to 72 hours or in whom symptoms rapidly progress. Incision and drainage becomes a consideration in these patients, but should be undertaken with caution as the facial nerve and Stenson duct may be inadvertently injured during the procedure. Confirmatory imaging is a prerequisite to operative intervention in these cases.

TABLE 40.5 CLASSIFICATION

NONNEOPLASTIC SALIVARY DISORDERS

Congenital
First Branchial Cleft Cyst
Lymphatic Malformation
Vascular Malformation
Granulomatous
Sarcoidosis
Infectious
Mumps
Hepatitis C
CMV
Tuberculosis
Cat-scratch Disease
Suppurative Sialadenitis
Other
Sialolithiasis
Sialadenosis
Juvenile Recurrent Parotitis

FIGURE 40.3. Axial CT scan demonstrating large bilateral hilar calculi of the submandibular glands. Stones of this size and location are generally not amenable to transoral or minimally invasive excision techniques. This patient underwent bilateral submandibular gland excision and recovered uneventfully.

Sialolithiasis is a disorder that merits special attention. Salivary stones are most commonly composed of calcium salts in the form of hydroxyapatite.^{7,9} They are typically seen in the context of chronic sialadenitis, though their exact pathogenesis remains unclear. Calculi may form in any of the major salivary glands, though 80% to 90% are submandibular.⁹ Patients typically present with recurrent, painful swelling of the submandibular region, often exacerbated at mealtimes. Noncontrast CT is the initial study of choice as nearly 90% of submandibular stones will be radio-opaque.^{7,10}

Treatment depends on the size and location of the calculus. Occasionally, small calculi will pass through the Wharton duct spontaneously. Initial therapy for small, distally situated stones consists of observation and sialogogues. Dilatation of the papilla and proximal end of the Wharton duct and may also be performed. Stones located proximal to the mylohyoid muscle are less likely to be amenable to transoral removal. However, recent advances in fiber optics have made transoral/transductal endoscopy (i.e., “sialendoscopy”) possible. Several endoscopic techniques are now used for this purpose and have been successful in treating proximal stones.⁹ Despite these advances, large, hilar, or intraglandular calculi are typically not amenable to transoral approaches (Fig. 40.3).¹⁰ In these cases, formal submandibular gland excision is usually necessary.

Pharyngitis

Pharyngitis is one of the most common reasons for ambulatory care visits in the United States today. Strictly defined, pharyngitis is an inflammatory process affecting the mucosa and submucosal structures of the throat. Bacterial infection with group A beta-hemolytic streptococci (GABHS) has classically been associated with pharyngitis (i.e., strep throat). However, only 5% to 15% of all adult cases of pharyngitis can be attributed to GABHS. The vast majority of cases are viral in origin.^{11,12} Other bacterial etiologies include non-group A

FIGURE 40.4. Schematic representation of a peritonsillar abscess. Purulence develops between the tonsillar capsule and the superior pharyngeal constrictor muscle. As a result, the palate bulges and the tonsil is deviated medially. Inflammation in the region of the pterygoid muscles results in pain and trismus, which may be significant.

streptococci, *Corynebacterium*, and *Neisseria* species, among others. Pharyngitis typically presents with sore throat and odynophagia. Bacterial tonsillitis is associated with purulent exudate, though this may also be seen in viral infections such as mononucleosis. Signs highly indicative of GABHS infection include fever, tonsillar exudates, tender cervical adenopathy, and the absence of a cough.¹² Patients with these signs and symptoms or in whom streptococcal testing is positive should be considered for antibiotic therapy with amoxicillin, erythromycin, or clindamycin.

Most pharyngitis is acute and self-limited, responding to supportive measures such as antipyretics, hydration, and, when indicated, antibiotics. However, bacterial pharyngitis may occasionally be complicated by a collection of purulent material in a potential space that lies between the tonsillar capsule and the superior constrictor muscle—the peritonsillar space. This space is contiguous with the retropharyngeal and parapharyngeal space.

Peritonsillar abscesses (PTAs) can potentially involve critical structures in these regions. Patients typically have a history of an antecedent pharyngitis. As pus collects in the peritonsillar space, symptoms may progress to severe sore throat, odynophagia, otalgia, and a “hot potato” voice.¹³ On exam, the oropharynx has an asymmetric appearance, with uvular deviation, medial displacement of the tonsil, and bulging of the soft palate on the affected side (Fig. 40.4). Trismus is a common feature. The diagnosis is clinical, though contrast-enhanced CT scan may be used in equivocal cases or if repeated aspirations fail to alleviate the symptoms. Needle aspiration, incision and drainage (I&D), and tonsillectomy have each been successfully used in the initial management of PTA.¹⁴ For cooperative adult patients without airway compromise, the authors favor a combination of bedside needle aspiration and I&D. After applying topical anesthesia, a 14-gauge needle is passed into the peritonsillar space and its contents aspirated. A number 11 scalpel is then used to create a cruciate incision centered on the needle entry point. This is enlarged and marsupialized using a hemostat. The remainder of the infected material is then evacuated. Antibiotic therapy with clindamycin or an extended-spectrum aminopenicillin is initiated.

Deep Neck Space Infections

The muscles and fascia of the neck divide it into a series of distinct but interconnected potential spaces commonly referred to as the deep neck spaces (Table 40.6). The intimate relationship that these spaces share with the airway, the great vessels, and the mediastinum underscores the importance of prompt recognition and management of deep neck infections (Fig. 40.5). Delays in diagnosis and treatment can be catastrophic as complications include airway obstruction, aspiration of ruptured

TABLE 40.6 CLASSIFICATION**DEEP NECK SPACES**

Spaces Involving the Entire Length of the Neck

abscess material, mediastinitis, necrotizing cervical fasciitis, jugular vein thrombosis, and carotid artery aneurysm or rupture.¹³ Fortunately, with the widespread use of antibiotics, the incidence of deep neck infections and their sequelae has declined.

Though classically associated with pharyngotonsillar disease, a growing number of deep neck infections are odontogenic in nature.¹³ Other risk factors include diabetes mellitus, immunocompromise, intravenous drug abuse, and branchial anomalies.^{13,15} A deep neck space infection should be suspected in any patient with the just-named risk factors who presents with neck pain and swelling.

The initial step in managing a patient with suspected deep neck infection is to ascertain the adequacy of the airway. Any signs of compromise should be addressed immediately by oral/nasal intubation or, alternatively, tracheostomy under

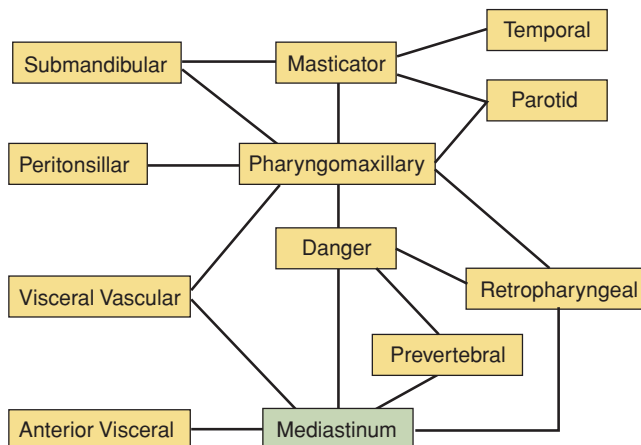

FIGURE 40.5. The deep spaces of the neck are distinct but interconnected compartments. Infections in any one of these may spread to involve other potential spaces and critical structures contained therein. (Adapted with permission from Gadre AK, Gadre KC. Infections of the deep spaces of the neck. In: Bailey BJ, Johnson JT, eds. *Head & Neck Surgery—Otolaryngology*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:670.)

local anesthesia. Once a secure airway has been established, a contrast CT scan should be obtained. This will help to better characterize the infection and will aid in surgical planning. Empiric therapy with broad-spectrum antibiotics should be initiated. Coverage should include beta-lactamase-producing and anaerobic species. Though a few patients will respond completely to intravenous antibiotics, surgical drainage is the definitive therapy. This may be accomplished transorally or transcervically. The choice of approach depends on the exact anatomic locale of the infection, but should provide the most direct access to the affected space while minimizing risk to surrounding structures. It must also allow for the complete exposure and drainage of the involved space(s) and débridement of any necrotic tissue.

Sinusitis

Sinonasal complaints are among the most common reasons for ambulatory care visits. Patients present with headache, facial/retro-orbital pressure, nasal congestion, anosmia, and purulent rhinorrhea. Though these features are suggestive of acute bacterial rhinosinusitis, they are by no means pathognomonic. In most patients, the etiologic agent is a community-acquired viral infection and the course of illness is self-limited.¹⁶ Bacterial growth is present in as few as one third of patients treated for sinusitis. The most common pathogens include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *S. aureus*.^{16,17} Diagnosis is based on the constellation of symptoms and the presence of purulent material during nasal endoscopy.

Although there are significant effects on quality of life during bouts of acute and chronic sinusitis, most cases will resolve without antibiotics and the vast majority of patients will convalesce without long-term consequences.^{16,18} However, the surgeon must be aware of the potential complications of acute suppurative sinusitis and their management. Complications of sinusitis may be grouped into three categories: local, orbital, and intracranial (Table 40.7).¹⁹ A high index of suspicion is

vital since many of these conditions can lead to significant morbidity and even mortality if left untreated. The presence of high fever, facial swelling, mental status changes, cranial neuropathies, proptosis, chemosis, or vision changes should alert the clinician to the presence of a complicated sinusitis. High-resolution CT scan of the brain and sinuses should be obtained along with ophthalmologic and/or neurosurgical consultation. Treatment consists of parenteral antibiotics and prompt surgical intervention aimed at relieving sinus obstruction and draining the infected material.¹⁹

Sinusitis in the context of an immunocompromised patient presents a particular challenge. Individuals with diabetes mellitus, HIV, or myelosuppression owing to chemotherapy or transplantation are at risk of developing fulminant invasive fungal sinusitis. Failure to recognize and treat these individuals in a timely fashion results in rapid deterioration and death. Even among appropriately managed patients, the mortality rates may be as high as 80%. Patients with intracranial involvement fare worse, with the condition being almost universally fatal.¹⁹ Diagnosis relies on clinical suspicion and the classic findings of black, necrotic tissue in the lateral nasal cavity on endoscopy. Biopsy and culture are required. The agents responsible for invasive fungal sinusitis include the Zygomycetes (*Mucor*, *Rhizopus*, and *Absidia* genera) and *Aspergillus* species. Histology reveals extensive necrosis and the presence of submucosal, perivascular, and intravascular hyphae on silver staining. The treatment involves aggressive surgical débridement that is extended until healthy, bleeding tissues are encountered. Craniotomy and orbital exenteration may be required. Long-term parenteral antifungal therapy and control of the underlying disease process are a must.

HEAD AND NECK NEOPLASIA

Neoplasms of the head and neck comprise a varied group of benign and malignant processes. While a handful of these diseases have no clear risk factors associated with them, a great number may be attributed to alcohol and tobacco use. Despite continued public health measures aimed at reducing the abuse of these substances, head and neck cancers remain prevalent throughout our society. Though there has been an overall reduction in the incidence rates over the past 30 years, mortality rates have shown more modest decreases during this period. In 2001, there were an estimated 75,000 new cases diagnosed and nearly 30,000 deaths attributable to head and neck cancers.²⁰

Continued advances in diagnosis, treatment, and reconstruction have improved our ability to manage these diseases. However, the oncologic, functional, communicative, cosmetic, and psychosocial implications of head and neck neoplasms continue to be a challenge. A systematic approach is vital to achieving success in any of these areas.

The following sections will review the salient features of the most common head and neck neoplasms and their management strategies.

Salivary Neoplasms

Tumors of the salivary glands constitute 3% to 6% of all head and neck neoplasms. The parotid gland is most commonly affected, with 65% of all tumors arising in it. An additional 8% of tumors will be seen in the submandibular gland while 27% occur in minor salivary glands.²¹ Most parotid and submandibular neoplasia is benign (75%–80% and 50%–60%, respectively). Conversely, more than 80% of all minor salivary gland tumors are malignant (Table 40.8). Patients with salivary tumors typically present with an asymptomatic mass. The presence of pain, trismus, or cranial neuropathy is suggestive of malignancy. Evaluation begins with a comprehensive history

and physical examination. Given that most of these masses represent benign tumors of the superficial parotid gland, superficial parotidectomy with dissection and preservation of the facial nerve is often undertaken without additional workup. However, malignancy may be present in the absence of the previously mentioned signs and symptoms. As a consequence, fine-needle aspiration (FNA) cytology is often used prior to surgical intervention. This test has predictive values in excess of 90%, and the results may be useful in surgical planning and patient counseling.²² MRI with contrast is the preferred imaging modality. This test can provide additional useful information about tumor size and position relative to the deep and superficial lobes of the parotid gland and may uncover multifocal disease (a feature present in nearly 10% of Warthin tumors).^{7,22}

Among the benign salivary neoplasms, pleomorphic adenoma (benign mixed tumor) is the most common, accounting for nearly 70%.⁷ Grossly, these appear as nodular, gray-tan masses. Though they appear to be well-circumscribed, histologic examination commonly reveals islands of tumor and pseudopodia extending into and beyond the capsule.²³ Simple enucleation of these tumors may result in their incomplete removal and eventuate in multifocal tumor recurrence. Appropriate surgical management therefore requires that they be widely excised to include a cuff of normal parotid tissue. The position of the facial nerve within the substance of the parotid gland necessitates its proximal identification and distal dissection during parotidectomy (Fig. 40.6). Superficial parotidectomy is the procedure of choice for nearly all benign parotid neoplasms.

Malignant salivary neoplasms are less frequent but require more aggressive therapy. They are staged according to their size and the degree of local extension (Table 40.9). Mucoepidermoid carcinoma is the most common malignancy of the parotid gland. These tumors are grouped by histologic grade, with low-grade tumors behaving in a more indolent fashion than intermediate and high-grade tumors. High-grade tumors demonstrate a prominent epidermoid component and smaller numbers of mucoid cells. Overall, high-grade mucoepidermoid carcinomas carry a poor prognosis. Rates of nodal and distant metastases may exceed 40% and 30%, respectively.²⁴

Surgery for malignant parotid tumors involves total parotidectomy. The facial nerve should be preserved except in cases of direct tumor extension or preexisting facial palsy.^{21,24}

Adenoid cystic carcinoma is the most common malignancy of the submandibular and minor salivary glands (Fig. 40.7).²¹ These tumors are characterized by their propensity for

FIGURE 40.6. Superficial parotidectomy. **A:** The standard Blair incision or the cosmetically superior rhytidectomy incision may be used. **B:** Branches of the facial nerve course between the superficial and deep lobes of the parotid. **C:** The main trunk of the facial nerve is identified 8 mm deep to the tympanomastoid suture line and at the same level as the digastric muscle. **D:** The nerve is then dissected distally, separating it from the substance of the parotid. **E:** Schematic representation of the relationship between the parotid and surrounding structures.

perineural spread. Up to 70% will exhibit this feature and skip lesions are common, resulting in a high local recurrence rate.²⁴ Adenoid cystic carcinomas are also marked by their unique natural history. Patients may experience 10- to 20-year disease-free intervals followed by a sudden and aggressive recurrence. Lung metastases are common, occurring in nearly half of all patients. Treatment consists of aggressive local therapy and adjuvant radiation with electron or neutron beam radiation.^{24,25} General principles regarding the management of salivary carcinomas are listed in Table 40.10.

Sinonasal Neoplasms

Various epithelial and mesenchymal tumors may arise within the sinonasal tract. Patients with sinonasal neoplasms will

TABLE 40.10 MANAGEMENT**GENERAL CONSIDERATIONS FOR TREATMENT OF SALIVARY GLAND MALIGNANCIES**

Malignant tumors of the parotid gland warrant total parotidectomy.

The facial nerve should be sacrificed only in cases of direct tumor invasion or preexisting facial paralysis.

Patients with high-grade tumors should undergo elective neck dissection.

Postoperative radiotherapy is indicated for all high-grade tumors; close margins; recurrent disease; skin, bone, nerve, or extraparotid extension; positive nodes; and unresectable tumors.

often present with recurrent epistaxis and unilateral nasal obstruction. Many will report having been treated for chronic sinusitis for several months prior to referral. Diagnosis is established by nasal endoscopy with biopsy. Imaging should include both high-resolution CT scan and a contrast-enhanced MRI. CT is used to evaluate for bony destruction whereas MRI is useful for differentiating tumor mass from inspissated secretions within the nose and sinuses. Approximately half of all sinonasal neoplasms are malignant, with squamous cell carcinoma accounting for nearly 80% of the cancers (these will be discussed in detail later in this chapter).²⁶ However, several benign lesions involving the nose and paranasal sinuses can exhibit aggressive behavior as well.

The most common benign sinonasal tumor is the papilloma. There are three categories of sinonasal papilloma (also known as schneiderian papillomas after the schneiderian mucosa lining the nasal wall): fungiform, cylindrical, and inverting.²⁷ Fungiform papillomas arise from the nasal septum, whereas cylindrical and inverting papillomas originate from the lateral nasal wall. Inverting papillomas are the most common variant. They are noteworthy for their significant propensity for recurrence

FIGURE 40.7. Excision of the submandibular gland. The skin incision usually is placed in a skin crease. **A:** After division of platysma, the ramus mandibularis is identified and retracted superiorly. **B:** Elevation of the gland allows identification of the lingual and hypoglossal nerves. After removal of the gland, the lingual nerve is in the base of the wound.

and for the fact that up to 20% will harbor in situ or invasive squamous cell carcinoma.²⁶ Consequently, removal of these lesions should be aggressive. Wide excision using a lateral rhinotomy approach and medial maxillectomy provides the greatest chance of cure, with recurrence rates ranging from 0 to 30%.²⁷ Advances in endoscopic instrumentation and techniques over the past decade have allowed for complete excision of these lesions through minimally invasive transnasal approaches. At centers experienced in endoscopic resection, the rates of disease control meet and in some cases exceed those achieved through open maxillectomy.²⁸

Juvenile nasal angiofibromas (JNAs) are benign vascular tumors found in the adolescent male population. These patients present with unilateral nasal obstruction with recurrent bouts of epistaxis. Many will require repeat transfusions. Recurrent epistaxis in a young or adolescent male necessitates a formal endonasal and nasopharyngeal exam. On endoscopy, these appear as friable masses along the lateral nasopharyngeal wall. They are thought to originate near the sphenopalatine foramen. Though histologically benign, these lesions may expand into the pterygopalatine fossa, nasal cavity, orbit, and skull base—leading to pain, swelling, trismus, cranial neuropathies, and vision changes.^{26,29} Management involves complete excision via a transpalatal or transmaxillary approach. Surgery is often complicated by profuse bleeding, and preoperative embolization is recommended. Endoscopic-transnasal approaches have demonstrated safety and efficacy in the management of JNA. These techniques continue to be investigated, but in expert hands it appears that they may impart better cosmetic outcomes, reduced blood loss, and shorter hospital stay.³⁰

Squamous Cell Carcinoma

4 In many ways, squamous cell carcinoma has become synonymous with head and neck cancer. Indeed, 80% to 90% of non-thyroidal/nonsalivary head and neck cancers are squamous cell carcinomas.^{2,20} Most of these tumors occur at readily visible or palpable sites.²⁰ Despite this, many patients delay seeking treatment and present with advanced disease—thereby dramatically reducing the chance of cure. With earlier diagnosis, many of these individuals might otherwise be rendered free of disease. Educating patients and physicians about the risk factors and signs associated with head and neck cancer is imperative to the process of early detection.

As with any other patient, the diagnostic evaluation of an individual with head and neck cancer begins with the history and physical examination (the critical elements of which were detailed previously). Once suspicion of a cancer exists, tissue diagnosis is required for confirmation. In some instances, this may be possible in the outpatient setting. As mentioned earlier, 75% of head and neck cancers occur at readily visible or palpable sites. Mucosal sites may be sampled by excisional biopsy whereas fine-needle aspiration may be used to sample lymph nodes or other subcutaneous masses. Alternatively, biopsy can be undertaken under general anesthesia as a component of a staging endoscopy procedure (*panendoscopy*). Panendoscopy involves direct laryngoscopy, esophagoscopy, and tracheobronchoscopy. In addition, it provides the surgeon with the opportunity to perform bimanual examination under anesthesia. Panendoscopy is the gold standard with respect to providing a detailed evaluation of the mucosal surfaces of the upper aerodigestive tract and should be performed for all patients with suspected head and neck cancers. Not only does it facilitate accurate staging and surgical planning, but it also allows for the detection of occult synchronous primary tumors.

Second primary tumors are common in the context of head and neck cancer and occur in approximately 20% of patients (published reports range from ~5%–~35%).³¹ Second primary tumors are more likely in heavy tobacco users (>20 pack

years), patients diagnosed before age 60 years, patients with oropharyngeal cancers, and among those with early-stage disease at initial presentation.^{31,32} Among patients with nonlaryngeal primary head and neck tumors, synchronous lesions are most often found on the mucosal surface of other upper aerodigestive tract subsites. The lung and mainstem bronchi are the most frequently affected locations in the context of laryngeal carcinoma.³³ The development of a synchronous or metachronous primary tumor imparts a dismal prognosis. Mortality rates in excess of 80% can be expected in the presence of a second primary head and neck cancer. If the second primary tumor develops in the lung or esophagus, the probability of survival drops to less than 5%.³²

The findings on panendoscopy are coupled with the outpatient examination and the results of imaging studies, and the patient is then staged according to the TNM classification and the American Joint Committee for Cancer (AJCC) staging system (Table 40.11).

GENERAL PRINCIPLES IN THE MANAGEMENT OF HEAD AND NECK CARCINOMA

Once histopathologic confirmation has been obtained and the patient has been clinically staged, the process of designing and carrying out a treatment plan is undertaken. This begins by having an open and frank discussion with patients about therapeutic options, risks, outcomes, and expectations. Many will not comprehend the gravity of their situation or the possibility of adverse functional and cosmetic outcomes arising as a result of curative therapy. Conversely, some will not recognize the potential for oncologic success nor will they be cognizant of the potential for aesthetic and functional reconstruction and rehabilitation. Patient and family support groups exist at most centers where head and neck cancers are treated. These are an invaluable and often underused resource for patients and physicians alike.

Given the complexity of modern treatment paradigms for head and neck cancers, most centers have instituted multidisciplinary tumor boards from which therapeutic plans are derived for each individual patient. Specific plans outlined will differ based on a given patient's tumor characteristics, functional status, potential for rehabilitation, and comorbidities.

Individual and institutional resources, customs, and biases also come into play. However, the principal goal in treating any head and neck cancer is to completely and permanently eradicate the disease. Treatment should be carried out in a manner that limits potential functional consequences to the greatest degree possible (without compromising the chance for cure).

The mainstays of treatment in head and neck cancer are surgery, external beam radiation therapy, and systemic chemotherapy. As a general rule, single-modality therapy is highly effective for early cancers (stages I and II). By definition, stages I and II carcinomas represent small, localized tumors without evidence of cervical metastases. This is true for all mucosal subsites within the head and neck. These are readily treated by surgery or radiation therapy and have a favorable prognosis. Among stages I and II head and neck tumors, survival rates exceed 80% after either definitive radiotherapy or surgery.³⁴ The decision to use surgery or radiation therapy depends on the tumor subsite, the expertise of the surgeon and radiation oncologist, and the preference of the patient. Surgical treatment provides immediate cure and allows radiation therapy to be reserved for future needs (i.e., recurrent disease, second primary tumors, etc.). Radiation carries with it a significant time requirement (standard head and neck protocols call for approximately 6 weeks of daily treatments). However, it avoids the removal or recontouring of anatomic structures that is associated with surgical resection. This has made radiation therapy a popular alternative for tumors in functionally sensitive areas such as the glottic larynx.

In contrast to stages I and II carcinomas, later-stage disease requires sequential or concomitant therapy using two and sometimes three different treatment modalities. In most cases, these tumors exhibit locally aggressive features or have metastasized to regional lymph nodes. Though radical resection is typically used with curative intent, there is a potential for microscopic residual disease even after all gross disease has been removed. In this context, adjuvant therapy is aimed at sterilizing any remaining viable tumor. Classically, external beam radiation therapy was used for this purpose. Indications for postoperative radiation therapy include locally advanced (T3 or T4) primary tumors, high-grade histology, perineural or vascular invasion, positive or close resection margins, N2 or N3 disease, and extracapsular nodal extension.³⁴ In 2004, the results of two separate prospective trials comparing the effects of adjuvant radiation therapy to adjuvant chemoradiotherapy were published simultaneously. Among high-risk head and neck cancers (i.e., with extracapsular nodal extension, multiple positive lymph nodes, or positive resection margins), both found that adjuvant chemoradiation significantly improved locoregional control. Survival was also improved in both, though to a statistically significant degree in only one of the two.^{35,36}

In rare instances, tumor volume, invasiveness, or proximity to critical structures may render it unresectable. In such circumstances, the potential for morbidity and/or mortality exceeds the reasonable probability of cure. Examples include circumferential encasement of the common or internal carotid artery, extensive skull base masses with multilevel cranial nerve or brain parenchyma involvement, and invasion of the prevertebral fascia or cervical spine. Likewise, distant metastases (including isolated dermal metastases) point to the presence of an advanced disease state for which cure is unlikely. In selected cases, resection may be undertaken for palliative purposes. However, for the vast majority of these stages IVb and c cancers, palliative chemotherapy and/or radiation therapy is the most appropriate option.

Several factors contribute to the overall prognosis among head and neck cancer patients. Many of these are inherent to the TNM staging system. Tumor size and invasiveness correlate to the risk of nodal metastases and assist with determining the need for elective neck dissection. The number, size, and

location of cervical metastases are predictive of regional recurrence and distant metastases. Distant metastases, in turn, are almost universally incurable. However, a recent report does demonstrate improved survival among patients undergoing resection of lung metastases versus those receiving conservative measures.³⁷ Though previous attempts at metastasectomy have not yielded positive results, these findings have sparked optimism and warrant further investigation.

Other patient and tumor characteristics associated with poor outcome include positive resection margins; perineural, vascular, or extracapsular nodal extension; African American race; malnutrition; anemia; and multiple medical comorbidities. Continued tobacco and alcohol use have significant effects on patient outcomes. Patients who abstain from tobacco have better locoregional control rates and are 2.5 times more likely to survive than those who continue to smoke. Smoking and alcohol cessation also significantly reduces the risk of second primary tumors.³⁸

Management of the Neck in Head and Neck Cancers

Neck masses are among the most common presenting signs and symptoms in patients with head and neck cancer. After determining the site of the primary tumor, attention should be paid to the size, number, and location of cervical metastases. These are essential components of the TNM staging system (Table 40.12). The nodal stage of a tumor provides important prognostic information. In the presence of even a single cervical metastasis, the stage can be no lower than III—regardless of the primary tumor size. As the number of involved nodes increases, there is a significant and stepwise decrease in recurrence-free and overall survival that is highly statistically significant.³⁹

Head and neck cancers have well-established lymphatic drainage patterns. In the absence of a known primary tumor, the location of cervical adenopathy may suggest the site of origin (Table 40.3). Alternatively, if the pattern of lymph node enlargement does not correspond to the mucosal site in question, the possibility of an occult second primary tumor should be considered.⁵

Much like primary tumors, early-stage cervical adenopathy (i.e., N0 or N1 disease) may be sterilized with single-modality therapy. In the N0 or N1 neck, surgery and radiation therapy are equally efficacious for this purpose. The neck must be addressed with one of these modalities when it is clinically positive (N1) or when the risk of occult metastases in an N0

patient exceeds 20%. This risk varies by T stage and subsite and will be discussed under the individual tumor site headings that follow. Table 40.13 provides general subsite and stage-specific indications for elective neck dissection in the context of a clinically negative neck. The decision to use radiation therapy or surgery depends to some extent on which modality has been chosen to treat the primary site. Radiation therapy avoids the potential risks of neck dissection and obviates the need for general anesthesia. However, selective neck dissection is acceptable in these cases. In experienced hands, selective neck dissections are of low morbidity and have the distinct advantage of providing tissue for accurate pathologic staging (Fig. 40.8).

In advanced nodal disease (N2 or N3) and in cases where extracapsular extension is present, combination therapy is used. More extensive neck dissection is required in these cases and is typically followed by adjuvant radiation or chemoradiation. The modified radical neck dissection is the procedure of choice for clinically positive disease. This procedure can take one of three forms, depending on the extent of the patient's disease.⁴⁰ Table 40.14 describes various neck dissections and the structures that are removed during each modification.

FIGURE 40.8. Intraoperative photograph demonstrating the left neck after performance of a selective (supraomohyoid) neck dissection. Selective neck dissection is generally a low-morbidity procedure. Vital structures such as the internal jugular vein (IJV), common carotid artery (CCA), and spinal accessory nerve (*large arrow*) are carefully preserved. In the context of an N0 neck, other nonvital structures such as the sternocleidomastoid muscle (SCM), external jugular vein (EJV), greater auricular nerve (GAN), cervical sensory rootlets (*small arrows*) and ansa cervicalis (*asterisks*) may also be spared.

One unique entity that should be discussed is the cystic neck mass. When seen in adults, these are commonly assumed to be benign lesions such as branchial cleft cysts and are managed with simple excisional biopsy. However, a large series of patients with isolated cystic neck masses revealed that approximately 10% harbored squamous cell carcinoma. This number is significantly higher among patients older than 40 years of age—approaching 25%.⁴¹ Cystic cervical metastases are most often observed with primary tumors of the Waldeyer ring and strongly associated with HPV.⁴² Fine-needle aspiration biopsy is the preferred initial diagnostic modality in these cases. If the cytology is benign, an open biopsy may be performed, but frozen section should be used. In the presence of carcinoma, the patient should undergo formal neck dissection and panendoscopy with directed biopsies and tonsillectomy *at that setting*.

HEAD AND NECK CANCER MANAGEMENT BY SUBSITE

Sinonasal Carcinomas

Squamous cell carcinomas (SCC) involving the sinonasal tract may occur in association with inverting papillomas or may be secondary to environmental exposures. In addition to tobacco smoke, occupational exposure to heavy metals such as nickel and hydrocarbons such as those used in the leather tanning and textile industries have been implicated. Chronic wood-dust exposure is associated with the development of sinonasal adenocarcinomas. However, these occur far less frequently than squamous cell cancers.^{26,27} Most sinonasal SCCs (approximately 60%) arise in the maxillary sinuses. Approximately one third are found on the lateral nasal wall, whereas 10% are ethmoidal. Primary carcinomas of the frontal and sphenoid sinuses are rare and constitute less than 2% of all sinonasal cancers.²⁶ Staging of these tumors follows the AJCC criteria (Table 40.15). Surgical resection is the preferred treatment for cure of sinonasal cancers. Cervical lymph node metastases are rare except in advanced-stage disease. Elective treatment of the neck is not indicated for T1 and T2 tumors. The approach to and extent of surgical resection depends on the location and stage of the primary tumor. For maxillary sinus tumors, options include partial or total maxillectomy

TABLE 40.14**CLASSIFICATION****CLASSIFICATION OF NECK DISSECTIONS**

Radical neck dissection	Lymph node levels I–V, SCM, IJV, and XI are removed
Modified radical neck dissection (MRND)	Node-bearing tissues from levels I–V are removed, but at least one of the above mentioned nonlymphatic structures is spared
MRND type I	Removal of levels I–V, SCM, IJV
MRND type II	Removal of levels I–V, IJV
MRND type III	Removal of levels I–V only
Selective neck dissections	Fewer than levels I–V are removed
Supraomohyoid neck dissection

SCM, sternocleidomastoid; IJV, internal jugular vein; XI, spinal accessory nerve.

with or without orbital exenteration. Ethmoidal tumors require external ethmoidectomy via anterior subcranial or mid-face degloving approaches. Significant cranial base involvement necessitates a combined approach with neurosurgery (i.e., craniofacial resection). The orbit may be preserved in cases

without radiographic or clinical evidence of direct invasion. However, if the apex, orbital fat, extraocular muscles, or eyelids are involved, exenteration is indicated.⁴³ As with the benign sinonasal tumors, an increasing body of literature suggests that endoscopic surgery is a safe and effective alternative

TABLE 40.15**STAGING****AJCC STAGING CLASSIFICATION FOR TUMORS OF THE NASAL CAVITY AND PARANASAL SINUSES**

Maxillary Sinus	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor limited to the maxillary sinus mucosa with no bony erosion
T2	Tumor erodes into the hard palate or middle meatus of the nose. Tumor does not involve the posterior maxillary wall or pterygoid plates
T3	Tumor invades any of the following: posterior wall of the maxillary sinus, subcutaneous tissues, floor or medial wall of the orbit, pterygoid fossa, or ethmoid sinuses
T4a	Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid sinus, or frontal sinus
T4b	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerve other than V2, nasopharynx, or clivus
Nasal Cavity and Ethmoid Sinuses	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor restricted to any one subsite with or without bony invasion
T2	Tumor invading two subsites within a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumor invades the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal invasion of anterior cranial fossa, pterygoid plates, sphenoid sinus, or frontal sinus
T4b	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V2, nasopharynx, or clivus

From: American Joint Committee on Cancer. *Cancer Staging Manual*, 6th ed. New York: Springer-Verlag; 2002, with permission.

to open approaches.⁴⁴ Adjuvant radiation therapy is reserved for patients with advanced-stage disease (i.e., those with skull base, orbital, pterygopalatine fossa or infratemporal fossa invasion). Five-year disease-specific survival among these tumors is approximately 50%.⁴⁴

Oral Cavity Carcinomas

Oncologically, the oral cavity extends from the vermillion border to the anterior tonsillar pillar. It is divided into eight distinct subsites including the lips, buccal mucosa, maxillary and mandibular alveoli, mobile tongue (i.e., tip of the tongue to the linea terminalis and circumvallate papillae), floor of mouth, hard palate, and retromolar trigone. The AJCC staging classification scheme for oral cavity tumors is presented in Table 40.16. Oral cavity carcinomas can be debilitating with regard to speech and deglutition. Functional and aesthetic reconstruction and rehabilitation present unique challenges among this patient population.

The oral tongue is the most common site of origin, accounting for 38% of all oral cavity carcinomas. This is followed by the floor of mouth and the lips (26% and 18%, respectively). Each of the remaining subsites constitutes a small overall percentage.⁴⁵ The following section reviews the management of the most frequently encountered oral cavity carcinomas.

Oral Tongue. Early-stage oral tongue lesions may be treated with transoral partial glossectomy. Given the lack of fascial barriers to spread within the tongue musculature, wide excision with 2-cm margins is advised. Advanced-stage tumors may require mandibulotomy for exposure or in some cases mandibulectomy and composite resection. Primary closure, healing by secondary intention, or split-thickness skin grafting may be used for small defects. Tethering of the tongue to the floor of the mouth should be avoided. To provide adequate bulk and mobility for speech and food bolus propulsion, hemi-tongue or larger defects should be reconstructed with regional or microvascular free flaps.

Because of its rich vascularity, lesions of the oral tongue tend to grow rapidly and develop early occult metastases. Nearly 40% of patients with T1 and T2 oral tongue carcinomas

will have developed occult nodal disease at the time of presentation.⁴⁶ This may be related to the depth of tumor invasion as lesions with greater than 2 mm thickness have nearly four times the rate of nodal metastases of thinner tumors (47% vs. 12%).⁴⁷ At present, elective neck dissection is indicated for all but the most superficially invasive T1 tumors.⁴⁸ Bilateral lymphadenectomy should be performed for lesions approaching the midline. The prognostic significance of nodal metastases cannot be overstated. Five-year survival is approximately 75% among patients with localized disease. In the presence of advanced T-stage or regional nodal metastases, this drops to 25% to 48%.^{45,49}

Floor of Mouth. As with the oral tongue, floor of mouth cancers have a high propensity for early nodal metastases. Though nearly 60% of patients will be clinically N0 at presentation,⁵⁰ nearly 21% with T1 disease and 62% with T2 tumors will harbor occult metastases.⁵¹ Likewise, the risk of regional lymphatic spread is correlated to the depth of invasion at the primary site.⁵² Elective neck dissection is thus advocated even in the case of T1 disease. Bilateral neck dissection should be performed for tumors approaching midline. In addition, bilateral neck dissection is recommended for patients with bulky (T3/T4) tumors and in patients with clinically positive ipsilateral nodes as the incidence of occult contralateral disease is approximately 21% and 36%, respectively.⁵³ Involvement of the submandibular gland may also occur in these tumors. This may result from direct invasion by bulky, aggressive tumors, but also indirectly along the submandibular duct. Many of these cancers are in close proximity to the Wharton duct papilla. This provides a preformed pathway for even the smallest floor of mouth lesions. Consequently, it is recommended that the ipsilateral submandibular gland be excised along with the primary tumor and neck contents.

Surgery is the treatment of choice for floor of mouth cancers. Local resection with or without adjuvant radiation therapy provides superior disease control to radiation therapy alone for early-stage tumors.⁵⁰ If the resection is limited to the mucosa and submucosa, split-thickness skin grafts may be used to resurface the floor of mouth and ventral tongue with excellent functional outcomes. In advanced disease, treatment typically involves composite resection—in many cases including glossectomy and mandibulectomy. Adjuvant radiation or chemoradiation is used in such cases. These patients typically require microvascular free flap reconstruction. Composite flaps such as the osteocutaneous fibular free flap are often used for this purpose, allowing for re-establishment of the bony mandibular contour and excellent functional outcomes. The 5-year disease-specific survival for floor of mouth carcinomas is 72% for stage I disease, 63% for stage II, 44% for stage III, and 47% for stage IV.⁵⁰

Lip. The lip is the third most common site for cancer in the oral cavity.⁴⁵ Squamous cell carcinoma accounts for 90% of these lesions.⁵⁴ The lower lip is affected much more frequently than the upper lip, with nearly 95% of cases involving the former.^{55,56} Most of these patients present with local disease, and the long-term prognosis is excellent. The actuarial 5-year overall survival for lip cancers is in excess of 90%.⁴⁵ Treatment is typically surgical and involves full-thickness resection with wide margins. If resection involves less than one third of the lip, primary closure or w-plasty may be used. However, larger defects that involve up to two thirds of the lip require local flaps such as the Karapandzic, Abbe, or Estlander. If more than two thirds of the lip is removed, more complex reconstruction such as the Bernard-Burrows, or, in some cases, microvascular free flaps are needed. The goal of lip reconstruction is to maintain oral competence while minimizing microstomia. Meticulous technique in reapproximating the vermillion border is a must.

Lymph node metastases in lip cancers are exceedingly rare. Most patients will present with T1 and T2 lesions, and among

TABLE 40.16 STAGING

AJCC STAGING CLASSIFICATION FOR TUMORS OF THE LIP AND ORAL CAVITY

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor is 2 cm or less in greatest dimension
T2	Tumor is greater than 2 cm, but <=4 cm in greatest dimension
T3	Tumor is greater than 4 cm in greatest dimension
T4	(Lip) Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or facial skin (cheek or nose)
T4a	(Oral Cavity) Tumor invades adjacent structures: e.g., through cortical bone, into deep (extrinsic) muscle of tongue (genioglossus, hyoglossus, palatoglossus, styloglossus), maxillary sinus, skin of face
T4b	(Oral Cavity) Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery

these lesions, the incidence of occult nodal metastasis is less than 5%. However, in patients with T3 and T4 tumors, the rate nears 25%. Tumors involving the oral commissure also have elevated rates of occult cervical lymph node involvement that is independent of T stage.⁵⁵ Elective neck dissection should be performed for patients with clinical evidence of disease and also for those with bulky primary tumors and those involving the oral commissure.

Oropharyngeal Carcinomas

The oropharynx extends from the anterior tonsillar pillars and the junction of the soft and hard palate to the level of the hyoid bone. Oropharyngeal subsites include the palatine tonsils, base of tongue, soft palate, and posterior oropharyngeal wall. The current primary tumor staging is listed in Table 40.17. Nearly 90% of oropharyngeal cancers are squamous cell carcinomas.⁵⁴ The symptoms of oropharyngeal carcinomas are typically vague, and primary tumors may be difficult to assess. Consequently, delay in diagnosis is common and nearly 70% of patients will present with advanced disease.^{45,54} Because of the rich vascularity of this region and bilateral lymphatic drainage patterns, these patients often develop bilateral or even contralateral nodal metastases. The tonsillar fossa is the most common site for primary tumors of the oropharynx, followed closely by the base of tongue. Primary tumors of the soft palate and posterior oropharyngeal wall occur much less frequently.

For early-stage, localized disease, surgery and radiation have approximately equal cure rates, with nearly 90% local control rates for the pooled group of oropharyngeal cancers.^{57,58} Ablative surgery of the oropharynx—particularly the tongue base—can have significant effects on speech and swallowing. Radiation therapy results in less functional impairment and is in most cases the preferred initial treatment for T1 and T2 tumors. Advanced-stage disease is typically treated with multimodal therapy including surgery with adjuvant radiation or chemoradiation. Among all head and neck sites, surgical resections of the oropharynx are the most likely to result in functional morbidity with respect to speech, deglutition, and management of airway secretions. Historically, tongue base resections very often necessitated the performance of a total laryngectomy as a means to prevent chronic aspiration. For several years, pedicled pectoralis major myocutaneous flaps were used to offset some of these difficulties. However, these have fallen out of favor because of pedicle retraction, unpredictability of residual bulk, and their insensate nature. As

reconstructive surgery has grown more sophisticated, microvascular free flaps have supplanted their use and have become the gold standard for oropharyngeal reconstruction. Microvascular free flaps have resulted in approximately 80% to 90% of patients returning to a normal diet. Conversely, this figure is approximately 40% to 50% after pedicled myocutaneous flaps.⁵⁹

For patients with localized disease, the 5-year overall survival is approximately 73%. However, this drops to less than 40% among patients with regional lymph node involvement.⁴⁵ Five-year survival for tongue base carcinomas is approximately 67% for stages I and II, 66% for stage III, and 50% for stage IV.⁵⁸ These numbers are slightly better for tonsil carcinomas, where survival is approximately 80% among patients with stages I and II disease and 40% to 50% for stages III and IV.⁶⁰

Recent data suggest that definitive chemoradiation may provide similar rates of disease control and survival to those historically observed for standard sequential therapy (surgery plus radiation).⁶¹ This approach is thought to provide superior functional outcomes.⁶² However, long-term quality of life scores are remarkably similar between chemoradiated patients and those treated with surgery followed by free flap reconstruction.⁶³

An increasing body of evidence implicates human papilloma virus (HPV), particularly HPV-16, in the pathogenesis of oropharyngeal squamous cell carcinoma.^{4,64} Approximately 50% of oropharyngeal cancers have been shown to contain HPV DNA. Though histologically similar, HPV-positive and HPV-negative squamous cell cancers differ with respect to their pathogenesis, patient characteristics, and clinical behavior. Patients with HPV-positive tumors tend to have a better overall prognosis. Cancer-related mortality may be reduced by up to 80% when compared to patients with HPV-negative tumors.⁶⁴ These data seem to suggest that HPV-positive and HPV-negative oropharyngeal cancers are distinct disease processes. However, the therapeutic implications of this are yet to be determined.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is a relatively uncommon diagnosis in the United States, though it is prevalent in other parts of the world—particularly in Southern China, where the disease is endemic. The risk of NPC remains elevated in patients who have emigrated from these areas, suggesting that both environmental and genetic factors contribute to its pathogenesis.⁶⁵ Environmental agents include nitrosamines such as those present in cured meats and fish, cigarette smoking, formaldehyde, wood dust, and polycyclic hydrocarbons.⁶⁶ However, Epstein-Barr virus (EBV) is the most widely implicated etiologic agent. More than 90% of endemic NPC and over 60% of cases worldwide are associated with EBV.^{67–69} Though NPC is a squamous cell carcinoma, there are three distinct histologic classifications based on the degree of differentiation: keratinizing, nonkeratinizing, and undifferentiated. The World Health Organization (WHO) has designated these as types I, II, and III, respectively. WHO type III is the most common, accounting for 63% of North American cases and 95% of endemic cases in China. In China, types I and II account for less than 5% of all cases. However, WHO type I NPC occurs much more frequently in North America, where up to 40% of the cases may be of the keratinizing variety.^{70,71} Endemic/EBV-associated NPC is typically WHO types II and III whereas sporadic NPC is most frequently keratinizing (type I). However, molecular detection methods have identified EBV DNA among a significant proportion of type I NPCs as well.⁷²

The most common presenting symptom of a patient with NPC is a neck mass. This is followed closely by nasal obstruction and otologic complaints.^{65,68,73} Advanced disease may be

heralded by cranial neuropathies, headache, or mental status changes. These tumors most typically arise within the Fossa of Rosenmüller, an anatomic region situated in the superolateral nasopharynx—just above the torus tubarius. The close proximity of these masses to the eustachian tube orifice is responsible for the high prevalence of aural pressure, hearing loss, and serous otitis media among patients with NPC. Indeed, the presence of an unexplained unilateral middle ear effusion necessitates visualization of the nasopharynx (either via endoscopy or high-resolution imaging) to rule out NPC.

Diagnosis is confirmed by biopsy and should be followed by imaging of the temporal bones and skull base with MRI. This will allow for more accurate staging and treatment planning. The staging classification of NPC differs somewhat from that of other head and neck subsites, particularly with reference to cervical lymph node metastases (Table 40.18). Radiation therapy is the mainstay of treatment, though a recent phase III clinical trial suggests that concomitant chemoradiation provides improved locoregional control and disease-

specific survival among patients with the endemic form of the disease.⁷⁴ Survival is strongly correlated to the histologic type, with WHO type III disease having a better prognosis than types II and I, respectively. Five-year overall survival is approximately 68% for type III, 56% for type II, and 46% for WHO type I NPC.⁷⁰

Hypopharyngeal Carcinomas

The hypopharynx is a region that extends from the hyoid bone to the esophageal inlet and includes the pyriform sinuses, post-cricoid region, and posterior hypopharyngeal walls. Squamous cell carcinoma of the hypopharynx is extremely aggressive, and the prognosis is poor irrespective of the therapeutic regimen used. The use of tobacco and alcohol account for a great number of hypopharyngeal carcinomas. However, several other risk factors including Plummer-Vinson syndrome, Fanconi anemia, and gastroesophageal reflux disease have also been reported.^{75–77} Patients will typically present with dysphagia, odynophagia, and otalgia. In addition, the hypopharynx has a rich lymphovascular supply and nodal metastases are common. Nearly 65% will present with N+ disease and more than three fourths of patients with clinically negative necks will harbor occult metastases.^{78,79} Contralateral disease is frequent, especially among tumors approaching the midline and those with clinically positive disease on the ipsilateral side.⁷⁹

Hypopharyngeal tumors are not readily visible on routine examination. Coupled with the vagueness of the symptoms, this often results in a delay in diagnosis. Nearly 80% will present with stage III or IV disease.³⁴ The primary tumor staging system may be seen in Table 40.19.

Early-stage disease may be treated using either definitive radiation therapy or open partial pharyngectomy/partial laryngopharyngectomy.⁸⁰ Advanced disease requires a combined approach using surgery and adjuvant radiation or chemoradiation. Surgery typically involves total laryngopharyngectomy and flap reconstruction. The submucosal lymphatic plexus of the hypopharynx is extensive and allows for proximal and distal spread of disease. This often necessitates a wide margin that may extend beyond the thoracic inlet. In these cases, resection includes not only total laryngopharyngectomy but also esophagectomy. Gastric pullup or jejunal free flap reconstruction is necessary in this circumstance.⁸¹ Given the morbidity of these procedures and the dismal prognosis, organ-preservation

protocols are now frequently used in the management of advanced hypopharyngeal carcinomas. The overall survival is similar to that obtained after surgery and adjuvant radiation therapy.⁸² Published 5-year overall survival rates are approximately 58%, 43%, 31%, and 13% for stages I, II, III, and IV, respectively.⁸³

Laryngeal Carcinomas

Cancers of the larynx receive a great deal of attention among both the medical and the lay community. This is not surprising given the vital role that this organ plays in speech, swallowing, and respiration. The psychosocial implications of laryngeal disease and its varied therapies are significant. Indeed, quality of life issues are more evident here than perhaps for any other head and neck subsite. For this reason, functional preservation of the larynx has become central to treatment paradigms for laryngeal carcinomas. However, as with any head and neck tumor, eradication of disease remains the primary goal. Fortunately, modern protocols have allowed for organ preservation in a significant proportion of early and advanced laryngeal carcinomas. Among those patients who do undergo total laryngectomy, there are a host of options that provide for alaryngeal speech as well.

The larynx itself is divided into three subsites: the supraglottis, the glottis, and the subglottis. The supraglottic larynx extends from the root of the epiglottis in the vallecula down to the ventricle. It includes the epiglottis, aryepiglottic folds, arytenoid cartilages, and false vocal folds. The glottis is the space encompassed by the true vocal folds. Oncologically, this subsite includes the true vocal folds and the mucosal surfaces approximately 5 mm above and below them. The subglottis begins at the inferior extent of the glottis and extends 1 cm distally into the trachea.

Given that even small perturbations of normal laryngeal airflow will result in dysphonia, many laryngeal cancers will present at early stages. This is particularly true of glottic carcinomas. Given the relative ease of diagnosis and the curability of these early-stage lesions, any hoarseness present for more than 3 weeks should be evaluated by direct or indirect laryngoscopy. Other symptoms of laryngeal cancers include referred otalgia, hemoptysis, stridor, dysphagia, odynophagia, and a neck mass. Larger tumors may result in dyspnea and airway obstruction. Supraglottic and subglottic tumors are particularly prone to this, as they may not manifest (i.e., with hoarseness) until the primary tumor is at an advanced stage.

As a general rule, equal cure rates may be achieved for stages I and II disease using either radiation therapy or surgery as a single modality. Radiation therapy typically results in better functional outcomes and is typically the primary treatment of choice. Stages III and IV disease most often requires extended partial laryngectomy or total laryngectomy with adjuvant radiation or chemoradiation therapy. The functional and social consequences of total laryngectomy can be significant. As a consequence, organ-preservation protocols have been developed as an alternative to laryngectomy in these cases as well. The concept of organ preservation for laryngeal carcinoma was championed after the publishing of a landmark study conducted through the Department of Veterans Affairs.⁸⁴ This seminal study used induction chemotherapy (cisplatin plus 5-fluorouracil) and external-beam radiation therapy as an alternative to total laryngectomy with adjuvant radiation therapy for patients with advanced laryngeal carcinoma. The 5-year survival rates among the two groups were 42% and 46% ($p = \text{NS}$). However, it was found that nearly two thirds of the patients in the organ preservation arm had laryngeal preservation at 5 years. Subsequent studies have confirmed chemo/radiation as an oncologically equivalent but functionally superior treatment for advanced laryngeal carcinoma. Today, induction chemotherapy has largely been

replaced by concurrent chemoradiation therapy as it was found to provide even greater rates of laryngeal preservation.⁸⁵ However, patients must be carefully selected for organ preservation protocols as there is speculation that their indiscriminate use may be responsible for an overall decrease in survival observed in recent years.⁸⁶

Supraglottic Carcinoma. The supraglottic larynx accounts for approximately 32% of all laryngeal carcinomas.⁸⁶ Staging of these tumors is outlined in Table 40.20. Unlike other head and neck cancers, laryngeal tumor stage is not based on size. Rather, it includes information regarding the number of subsites involved, degree of functional impairment of the vocal folds, and involvement of surrounding structures. Even small tumors of the supraglottis may be advanced-stage lesions if they invade the pre-epiglottic space or cause vocal fold fixation. The supraglottis has a rich lymphovascular supply, which facilitates early bilateral nodal metastases even among small primary tumors. Although more than two thirds of patients will be clinically N0 at presentation,⁸⁷ the rate of occult metastases is 20%, 25%, and 40% among T2, T3, and T4 tumors, respectively.⁸⁸

Management of early supraglottic carcinomas may be through single-modality therapy with either radiation or surgery. Disease-specific survival for stage I and II supraglottic cancers are approximately 79% and 76%, respectively. Surgery for T1 and T2 supraglottic carcinoma involves open supraglottic laryngectomy. In recent years transoral laser resection has emerged as an alternative to the open procedure. Local control rates and disease-specific survival for T1 and T2 disease are equivalent to historical controls undergoing open supraglottic laryngectomy.^{89,90} Advanced-stage supraglottic carcinomas should be treated with a multimodal approach. Surgery with adjuvant radiation/chemoradiation or definitive chemoradiation may be used. Surgical resection classically involved total laryngectomy. Alternatively, selected T1 to T3 glottic, supraglottic, and transglottic tumors may be surgically addressed via the supracricoid laryngectomy. This procedure is a form of partial laryngectomy that involves removal of the entire thyroid cartilage, true vocal folds, and supraglottic larynx. The cricoid cartilage and at least one arytenoid cartilage are preserved. This allows for preservation of a limited but functional voice. However, these patients must be carefully selected as nearly all will experience some degree of chronic aspiration. Contraindications to supracricoid laryngectomy are fixation of the arytenoid, subglottic extent, cricoid invasion, extralaryngeal spread, and poor pulmonary reserve. In carefully selected patients at experienced centers, oncologic and functional results are similar to those obtained after total laryngectomy.⁹¹ Disease-specific survival rates for stages III and IV supraglottic carcinoma are 64% and 50%, respectively.⁸⁷

Glottic Carcinoma. Glottic carcinomas account for 51% of all laryngeal cancers.⁸⁶ Given that even small glottic tumors can have a significant impact on the voice, patients will frequently present with early-stage disease. The glottic larynx is devoid of lymphatics, and the incidence of nodal metastases is low in T1 and T2 disease. Elective neck dissection is reserved for patients with advanced primary tumors. Therapeutic neck dissection should be used for any clinically positive nodes. For early glottic cancers, radiation therapy or surgery may be used with equal cure rates. Disease-specific survival among T1 tumors ranges from 89% to 100%. Patients with T2 tumors fare slightly worse, with published survival rates ranging between 75% and 90%.^{86,92} From a surgical standpoint, open partial laryngectomy is the gold standard, with local control rates approaching 95% for T1 disease and 80% to 90% for T2.⁹² However, transoral laser resection results in similar rates of disease control with less overall morbidity. Voice outcomes tend to be similar after radiation or laser excision of T1 tumors, though radiation is superior in this regard when the

primary tumor is larger.⁹² Stages 3 and 4 lesions are managed similar to supraglottic tumors. Total laryngectomy and, in selected cases, supracricoid laryngectomy with bilateral neck dissection and adjuvant radiation/chemoradiation or definitive chemoradiation (in selected cases) may be used. Five-year survival for locally advanced stages III and IV glottic carcinoma is 60% and 53%, respectively. In the presence of regional nodal disease, these numbers decrease significantly.⁸⁶

Subglottic Carcinoma. Subglottic cancers represent 2% of all malignant laryngeal tumors. Consequently, there are limited data with regard to treatment and outcomes. The literature suggests that most patients present with advanced-stage disease and that the prognosis is dismal. Current recommen-

dations for stages I and II disease is definitive radiation therapy, with local control and survival rates of approximately 65% to 70%.^{93,94} Advanced disease often involves the thyroid gland, paratracheal lymph nodes, trachea, and other structures of the superior mediastinum. Total laryngectomy with tracheal resection and adjuvant radiation/chemoradiation are advocated. Despite aggressive local and systemic therapy, the prognosis is poor, with overall survival nearing 25%.⁹⁴

CHAPTER 41 ■ ESOPHAGEAL ANATOMY AND PHYSIOLOGY AND GASTROESOPHAGEAL REFLUX DISEASE

JEFFREY H. PETERS, VIRGINIA R. LITTLE, AND THOMAS J. WATSON

KEY POINTS

- 1 The lymphatics of the esophagus form a rich submucosal network draining into regional lymph nodes in the periesophageal connective tissue; thus, little barrier exists to the longitudinal spread of esophageal cancer.
- 2 The diagnosis of gastroesophageal reflux based on symptoms alone is correct in only approximately two thirds of patients because the symptoms are often nonspecific and can be caused by other conditions.
- 3 The three characteristics of the lower esophageal sphincter that maintains its resistance or “barrier” function to intra-gastric and intra-abdominal pressure challenges are pressure, overall length, and length exposed to the positive-pressure environment of the abdomen.
- 4 An important complication of gastroesophageal reflux is the development of reflux-induced respiratory symptoms either with or without heartburn.
- 5 Antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and reflux disease.
- 6 Factors predisposing to the development of Barrett esophagus include early-onset gastroesophageal reflux disease, abnormal lower esophageal and esophageal body physiology, and mixed reflux of gastric and duodenal contents into the esophagus.
- 7 Proton pump inhibitor therapy, both to relieve symptoms and to control esophagitis, is an acceptable treatment, although most patients will require life-long treatment.
- 8 Progression of nondysplastic Barrett epithelium occurs with 5% to 10% of patients per year progressing to dysplasia and 0.5% to 1% per year progressing to adenocarcinoma.
- 9 Until recently, esophagectomy was considered the standard of care for patients with high-grade dysplasia. With the Western acceptance of an Eastern modality, endoscopic mucosal resection is becoming an increasingly attractive option for patients with high-grade dysplasia and intramucosal cancers.
- 10 The standard of care for the treatment of confirmed Barrett esophagus with high-grade dysplasia has been esophagectomy because approximately 35% of patients will harbor invasive adenocarcinoma. Where expertise exists, endoscopic therapies such as endoscopic resection or mucosal ablation are being increasingly utilized in highly selected patients with high-grade dysplasia or early esophageal carcinoma.
- 11 The mainstay of maintenance medical therapy is acid suppression. Patients with persistent symptoms should be given proton pump inhibitors, such as omeprazole. In doses as high as 40 mg/d, they can effect an 80% to 90% reduction in gastric acidity. Such a regimen usually heals mild esophagitis, but healing may occur in only three fourths of patients with severe esophagitis.
- 12 Three factors predictive of a successful outcome following antireflux surgery are (a) an abnormal score on 24-hour esophageal pH monitoring; (b) the presence of typical symptoms of gastroesophageal reflux disease, namely, heartburn or regurgitation; and (c) symptomatic improvement in response to acid suppression therapy prior to surgery.

ANATOMY

A detailed knowledge of the anatomic relationships of the esophagus is essential for the surgeon to plan and perform safe surgery, as well as to understand the significance of abnormalities detected on studies such as upper endoscopy, barium roentgenography, or computed tomography.¹ In this section, the embryology of the esophagus is first described, then the topographic relations of the esophagus are covered, and finally the conduct of investigations that yield anatomic information is addressed.

The embryology of the esophagus is important in understanding the pathogenesis of congenital malformations of the esophagus and trachea. The embryonic esophagus forms when

paired longitudinal grooves appear on each side of the laryngotracheal diverticulum. These grooves subsequently grow medially and fuse to form the tracheoesophageal septum. This septum divides the foregut into the ventral laryngotracheal tube and the dorsal esophagus. Incomplete fusion of the two lateral grooves was thought to be the major factor in the pathogenesis of congenital tracheoesophageal fistula, but the anomaly is now attributed to abnormal growth and differentiation of the lung buds. Initially the esophagus is short, but elongation occurs rapidly, and the final relative length is attained by the seventh gestational week. This is followed by endodermal proliferation, resulting in near obliteration of the esophageal lumen and subsequent recanalization by the development of large vacuoles that coalesce. The striated muscle of

the upper esophagus is derived from the caudal branchial arches and is innervated by the vagus nerve and its recurrent laryngeal branches. The smooth muscle of the lower esophagus arises from splanchnic mesenchyme and is supplied by a visceral nerve plexus derived from neural crest cells. The adult position of the vagus nerves on the esophagus is the result of unequal growth of the greater curve of the stomach relative to the lesser curve, resulting in rotation of the left vagus anteriorly and the right vagus posteriorly.

The *cervical esophagus* begins below the cricopharyngeus muscle, which itself is a continuation of the inferior constrictor of the pharynx. The potential space between these muscles posteriorly is the site where Zenker diverticulum develops. The cervical esophagus is about 5 cm long. It begins at the level of C6 and extends to the lower border of T1, curving slightly to the left in its descent. Anteriorly, it abuts against the trachea and posterior larynx and can be dissected off both organs if necessary. Posteriorly, the retroesophageal space is continuous with the retropharyngeal space above and the superior mediastinum below. Laterally, the omohyoid muscle crosses it obliquely and is usually divided to gain access to the esophagus. The carotid sheaths lie laterally and the lobes of the thyroid and the strap muscles anteriorly. The recurrent laryngeal nerves lie in the grooves between the esophagus and the trachea. The right recurrent nerve runs a more oblique course and is more prone to anatomic variants. Consequently, although the surgical approach to this portion of the esophagus may be from either side of the neck through an incision along the anterior border of sternocleidomastoid muscle, the left side is chosen if possible.

The *thoracic esophagus* in its upper part is closely related to the posterior wall of the trachea. This close relation is responsible for the early spread of cancer of the upper esophagus into the trachea, and it limits the ability of the surgeon to perform an en bloc resection of such a tumor. Above the level of the tracheal bifurcation, the esophagus moves to the right of the descending aorta. It then moves to the left, passes behind the tracheal bifurcation and the left main bronchus, and descends to the diaphragm. In its lower third, the esophagus courses anteriorly and to the left to pass through the diaphragmatic hiatus. The lower esophagus is covered only by flimsy mediastinal pleura on the left, and it is this portion that is most commonly the site of perforation in Boerhaave syndrome. The azygos vein is closely related to the esophagus as it arches from its paraspinous position over the right main bronchus to enter

the superior vena cava. The thoracic duct ascends behind and to the right of the distal esophagus, but at the level of T5 it passes posterior to the aorta and ascends on the left side of the esophagus and posterior to the left subclavian artery.

Throughout its length, the attachments of the esophagus to its adjacent structures other than the posterior trachea are flimsy. This accounts for the ease with which the esophagus may be bluntly mobilized out of the mediastinum during transhiatal esophagectomy. In general, the lower esophagus is most easily approached through the left chest, but access to the supra-aortic esophagus is restricted. Thus, a left thoracotomy is most useful for performing Heller myotomy, transthoracic fundoplication, or resection of an epiphrenic diverticulum. Access to the entire thoracic esophagus can be obtained only from the right chest, but access to the intra-abdominal organs is restricted by the liver and normally requires a separate upper abdominal incision.

The abdominal esophagus begins as the esophagus enters the abdomen through the diaphragmatic hiatus (Fig. 41.1). It is surrounded by a fibroelastic membrane, the phreno-esophageal ligament, which arises from the subdiaphragmatic fascia (Fig. 41.2). The lower limit of the phreno-esophageal membrane anteriorly is marked by a prominent fat pad, which corresponds to the gastroesophageal (GE) junction. The lower esophageal sphincter (LES) is a zone of high pressure 3 to 5 cm long at the lower end of the esophagus.² Although it does not correspond to any macroscopic anatomic structure, its function appears to be related to the microscopic architecture of the muscle fibers. The esophageal hiatus is formed by the right and left crura, which form a sling of muscular fibers arising by tendinous bands from the anterolateral surface of the first four lumbar vertebrae. The relative contributions of the right and left crura to the sling are variable. Surgeons name the crura from their relation to the esophagus, whereas anatomists name them from their relation to the aorta. Thus, both right and left “surgical” crura originate from the right “anatomic” crus. Caudally, the crura are united by a tendinous arch, the median arcuate ligament, just anterior to the aorta at the level of the celiac axis.

The blood supply and venous drainage are largely segmental. The inferior thyroid artery provides the main blood supply to the cervical portion of the esophagus. This becomes important in a patient with a previous thyroidectomy, although ligation is usually performed distal to the esophageal branch. The thoracic portion of the esophagus receives its blood supply from two sources. Usually, branches from two to three

FIGURE 41.1. The diaphragm and esophageal hiatus viewed from below.

FIGURE 41.2. Attachments of the phreno-esophageal membrane.

bronchial arteries provide the proximal arterial supply, and branches directly from the aorta supply the more distal thoracic esophagus. The upper of these aortic branches arises between the sixth and seventh thoracic vertebrae; the lower one arises between the eighth and ninth thoracic vertebrae. Intrathoracic mobilization of the esophagus during the performance of antireflux procedures often requires ligation of these

branches. The abdominal esophagus receives its blood supply from branches of the left gastric artery and inferior phrenic arteries (Fig. 41.3). A particularly constant artery at the base of the left surgical crus connects the inferior phrenic artery to branches of the left gastric artery and is sometimes called the Belsey artery. It is often seen during the crural dissection in performing laparoscopic fundoplication. Once the vessels have

FIGURE 41.3. Arterial blood supply of the esophagus.

FIGURE 41.4. Venous drainage of the esophagus.

entered the muscular wall of the esophagus, branching occurs at right angles to provide a longitudinal vascular plexus. This anatomic arrangement allows for mobilization of the esophagus from the stomach to the aortic arch without ischemic injury.

A venous plexus in the submucosa collects capillary blood and delivers it into a periesophageal venous plexus. From this plexus, esophageal veins arise that empty into the inferior thyroid vein proximally; into the bronchial, azygos, or hemiazygos veins in the thorax; and into the left gastric vein in the abdominal region (Fig. 41.4). The left gastric vein, or coronary vein, provides the principal collateral in portal hypertension when esophageal varices develop. The submucosal veins become much more superficial in the most distal esophagus, 1 to 2 cm above the GE junction, and are consequently the most common site of bleeding in portal hypertension. The continuity between the submucosal venous networks of the esophagus and stomach provides an additional collateral pathway for portal blood to enter the superior vena cava through the azygos vein in patients with portal hypertension.

1 The *lymphatics* of the esophagus form a rich submucosal network draining into regional lymph nodes in the periesophageal connective tissue (Fig. 41.5). Thus, little barrier exists to longitudinal spread of cancer in the esophagus; it is estimated that for every 1 cm of axial spread, there are 6 cm of longitudinal spread. Lymphatic drainage from the upper two thirds of the esophagus is usually cephalad, but drainage from the lower one third is in both directions. In the cervical region, esophageal lymphatic drainage is toward the internal jugular and upper tracheal nodes. Posterior mediastinal nodes drain the thoracic portion of the esophagus dorsally. Drainage from the anterior portion of the thoracic esophagus is most often to tracheal nodes superiorly and subcarinal and paraesophageal

nodes inferiorly. In the abdomen, the esophageal lymph drains to cardiac and celiac nodes, which may eventually drain into the cisterna chyli or the thoracic duct. Although lymphatic metastases in the esophagus generally involve the regional nodes in proximity, nodal involvement may occur several centimeters away from the primary lesion because of the rich intramural lymphatic anastomotic channels. When a carcinoma is limited to the mucosa (above the muscularis mucosae), the incidence of lymphatic metastases is low, but once it spreads into the submucosa, the incidence rises to 50% to 60%. The results of three-field lymph node dissection for esophageal carcinoma have emphasized the widespread lymphatic connections within the esophagus.

The *innervation* of the cricopharyngeal sphincter and cervical portion of the esophagus is from both the right and left recurrent laryngeal nerves.² These nerves, arising from the vagus, travel dorsally around the subclavian artery on the right and the arch of the aorta on the left. Branching to both the esophagus and trachea occurs as these nerves ascend in the tracheoesophageal groove. The nerve may be injured during dissection of the upper esophagus in the neck or during the mediastinal dissection in transhiatal esophagectomy. Although much attention is given to the vocal cord dysfunction that accompanies recurrent laryngeal nerve damage, it is also clear that cricopharyngeal sphincter dysfunction and motility problems of the cervical esophagus can occur with injury to these nerves. Serious aspiration following recurrent nerve injury is caused not only by cricopharyngeal dysfunction, but also by the additional morbidity incurred because of inability to close the glottis during swallowing and loss of the protection afforded by effective coughing.

Branches from the left recurrent laryngeal nerve and from both vagus nerves provide innervation of the upper thoracic

FIGURE 41.5. Lymphatic drainage of the esophagus.

esophagus. The esophageal plexus on the anterior and posterior wall of the esophagus provides innervation for the lower esophagus. The esophageal plexus also receives fibers from the thoracic sympathetic chain. The single trunks located distally contain fibers from both right and left original vagus nerves.

Efferent preganglionic sympathetic fibers supplying the esophagus arise from the fourth to sixth thoracic spinal cord segments and terminate in the cervical and thoracic sympathetic ganglions. Fibers from the superior cervical ganglion arrive at the pharyngeal plexus by way of vagal nerves. The postganglionic fibers reach the esophagus by branches from the cervical and thoracic sympathetic chain. The distal esophageal segments also receive direct sympathetic fibers from the celiac ganglion.

Afferent visceral sensory pain fibers from the esophagus terminate without synapsing in the first four segments of the thoracic spinal cord, following both sympathetic and vagal pathways. Pain fibers from the heart also travel in this same pathway, which explains the similarity of the symptoms in many esophageal and cardiac diseases.

PHYSIOLOGY

The act of alimentation requires the passage of food and drink from the mouth into the stomach. Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Swallowing, once initiated, is entirely a reflex. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx.³ Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, as following a cerebral vascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue. The backward tilt of the epiglottis covers the opening of the larynx to prevent

aspiration. The whole pharyngeal part of swallowing occurs within 1.5 seconds.

During swallowing, the pressure in the hypopharynx rises abruptly to at least 60 mm Hg because of the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less-than-atmospheric mid-esophageal or intrathoracic pressure. This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost due to muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 second of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mm Hg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 41.6). The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed further down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

Swallowing can be started at will, or it can be elicited as a reflex by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through the 5th, 7th, 10th, 11th, and 12th cranial nerves, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 second. Little is known about the organization of the swallowing center except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebral vascular accident, this coordinated outflow may be altered, causing mild to severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function and predispose the patient to aspiration.

Pharyngeal activity in swallowing initiates the esophageal phase. Owing to the helical arrangement of its circular muscles, the body of the esophagus functions as a worm drive propulsive pump and is responsible for transmitting a bolus of food into the stomach. The esophageal phase of swallowing represents esophageal work done during alimentation in that food is moved into the stomach from a negative-pressure environment of -6 mm Hg intrathoracic pressure to a positive-pressure environment of 6 mm Hg intra-abdominal pressure or over a gradient of 12 mm Hg. Effective and coordinated smooth muscle function in the lower third of the esophagus is, therefore, important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30 to 120 mm Hg. The wave rises to a peak in 1 second, lasts at the peak for about 0.5 second, and then subsides in about 1.5 seconds (Fig. 41.6). The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3 to 5 seconds.^{4,5} The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2 to 4 cm per second and reaches the distal esophagus about 9 seconds after swallowing starts. Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut transversely, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. For this reason, a sleeve resection of the esophagus can be performed without destroying its normal function. Afferent

FIGURE 41.6. Representative example of manometric tracing of an esophageal peristaltic wave. Channel 2 is in the proximal esophagus and channel 5 is in the distal esophagus. The channels are 5 cm apart. The wave can be seen to progress in time down the esophagus.

FIGURE 41.7. Representative example of a manometric tracing of lower esophageal sphincter relaxation. Channels 2 and 3 are in the distal esophagus and show a peristaltic wave progressing downward. The lower four channels are all at the same level within the lower esophageal sphincter and oriented radially at 12, 3, 6, and 9 o'clock. The dotted lines below each tracing represent gastric baseline pressures. The lower four tracings each relax to gastric baseline at the initiation of the swallow.

impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought.

Despite the rather powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5 to 10 g. Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that, in humans, the sphincterlike function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch. The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow (Fig. 41.7). The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous LES relaxation, thought by some to be a causative factor in gastroesophageal reflux disease (GERD). The power of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction.

The LES has intrinsic myogenic tone, which is modulated by neural and hormonal mechanisms.^{6,7} α -Adrenergic neurotransmitters or beta-blockers stimulate the LES, and alpha-blockers and β stimulants decrease its pressure. It is not clear to what extent cholinergic nerve activity controls LES pressure. The vagus nerve carries both excitatory and inhibitory fibers to the esophagus and sphincter. The hormones gastrin and motilin have been shown to increase LES pressure; cholecystokinin, estrogen, glucagon, progesterone, somatostatin, and secretin decrease LES pressure. The peptides bombesin, B-enkephalin, and substance P increase LES pressure; calcitonin gene-related peptide, gastric inhibitory peptide, neuropeptide Y, and vasoactive intestinal polypeptide decrease LES pressure. Some pharmacologic agents such as antacids, cholinergics, domperidone, metoclopramide, and prostaglandin F_2 are known to increase LES pressure; anticholinergics, barbiturates, calcium channel blockers, caffeine, diazepam, dopamine, meperidine, prostaglandin E_1 and E_2 , and theophylline decrease LES pressure. Peppermint, chocolate, coffee, ethanol, and fat are all associated with decreased LES pressure and may be responsible for esophageal symptoms after a sumptuous meal.

During 24-hour esophageal pH monitoring, healthy individuals have occasional episodes of GE reflux. This physiologic reflux is more common when a person is awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position.

GASTROESOPHAGEAL REFLUX DISEASE

Definition and Epidemiology

Developing an accurate definition of gastroesophageal reflux disease is surprisingly difficult. The disease can be associated with myriad common gastrointestinal (GI) and respiratory symptoms and there is no fully accurate diagnostic test that can be relied upon. In an effort to provide a consensus definition, a group of experts came together in Montreal in 2004 and concluded that GERD can be best defined as “a condition

FIGURE 41.8. Time trends for the prevalence of weekly heartburn from 1980 to 2005. (Reproduced with permission from El-Serag H. Time trends of gastroesophageal reflux disease: a systematic review. *Clin Gastroenterol Hepatol* 2007;5:17–26, Figure 1.)

which develops when the reflux of stomach contents causes troublesome symptoms and/or complications.”⁸

GERD is a very common disease. Population-based studies have reported that one third of Western populations experience the symptoms of GERD at least once a month, with 4% to 7% of the population experiencing daily symptoms.^{9,10} Its prevalence varies considerably around the globe and is highest in North America, Australia, and Western Europe and lowest in Africa and Asia.¹¹ It is also likely that both the prevalence and severity of GERD are increasing in many parts of the world. Time trend analyses have shown that the prevalence of GERD symptoms has increased progressively in most longitudinal studies, including those from the United States, Singapore, and China (Fig. 41.8).¹² Further, recent data reported by the Agency for Healthcare Research and Quality (AHRQ) indicate a marked increase (103%) in hospitalizations for treating disorders caused by GERD; a 216% increase in hospitalization of patients who, in addition to the ailment for which they were admitted, have milder forms of GERD; and a 39% increase in admission for GERD with severe symptoms including anemia, weight loss, and vomiting.¹³ These data suggest that the current therapeutic approach to GERD may be inadequate.

Most patients with mild symptoms self-medicate with over-the-counter antacids or antisecretory agents, whereas those with more severe and persistent symptoms seek out medical attention. Further, the prevalence and severity of GERD are likely increasing. This is in contrast to duodenal ulcer disease, where the prevalence has markedly decreased (Fig. 41.9).¹⁴ The diagnosis of a columnar-lined esophagus is also increasing at a rapid rate, and deaths from end-stage benign esophageal disease are on an upward trend.¹⁵ These changes have occurred despite dramatic improvements in the efficacy of treatment options.

Two epidemiologic trends may be contributing to the increasing prevalence and severity of GERD over the past several decades. Population-based studies have shown that GERD is positively associated with obesity and negatively associated with gastric colonization with *Helicobacter pylori*. Over the past 20 to 30 years, the former has increased and the latter has decreased markedly in most Western countries. The relationship between GERD and body mass index (BMI) has been evaluated in a number of well-designed clinical studies. The frequency, duration, and severity of reflux symptoms were studied in 10,500 women of the Nurses’ Health Study and a dose-dependent relationship between increasing BMI frequency of GERD symptoms was identified.¹⁶ Compared to normal-weight women (BMI 20 to 22.4), underweight women (BMI <20) were one-third less likely and overweight women (BMI 25 to 27.4) two times more likely to have frequent GERD symptoms. Obese women (BMI >30) had a nearly three times higher risk of frequent GERD symptoms (Fig. 41.10). Recent meta-analyses confirm these findings, with studies from the United States demonstrating an association between increasing BMI and the presence of GERD.¹⁷ High-resolution motility studies have shown a significant correlation with BMI and both intragastric pressure and gastroesophageal pressure gradients, providing a physiologic explanation for the BMI–GERD association.¹⁸ These studies suggest that obese subjects are more likely to have esophagogastric junction disruption and abnormal pressure gradients favoring the development of reflux. Finally, the risk of Barrett esophagus has been correlated with the presence of central obesity. Measures of central obesity, including waist circumference and waist-to-hip ratios, were associated with both short- and long-segment Barrett esophagus, with a 4.1 higher odds ratio of long-segment Barrett in patients with a high waist-to-hip ratio.¹⁹

The possible pathogenic role of helical-shaped bacteria found in gastric fluids was first suggested in the late 19th century by the Polish scientist Walery Jaworski of the University of Krakow.²⁰ It was the publication of two Australian scientists in 1983 that convincingly demonstrated the pathogenic role of *H. pylori*.²¹ These pioneering studies of Barry Marshall and

Robin Warren from Perth, Australia, included self-experiments and were later awarded the Nobel Prize. *H. pylori* induces a significant inflammatory and immune response in the affected host, resulting in persistent inflammation in virtually all infected subjects.

The relationship between *H. pylori* and GERD has been of interest for decades. The observation that gastric mucosal atrophy was less frequent in patients with reflux esophagitis was made well before the *H. pylori* era. Evolutionary hypotheses assume, and the majority of available epidemiologic data show, that the decline of *H. pylori* infection is one of the reasons behind the increasing incidence of GERD-related diseases including esophageal and cardia adenocarcinoma in the Western world. This inverse relationship is strongest between *H. pylori* and esophageal adenocarcinoma, although significant evidence relates *H. pylori* and the development of Barrett esophagus and GERD. Over the period from 1970 to 1995, the incidence of both duodenal ulcer, compared to erosive esophagitis, and distal gastric cancer, compared to gastric cardia cancer, displays strikingly opposing time trends. It has been postulated that *H. pylori*-induced chronic corpus gastritis may protect against the development of gastroesophageal reflux disease and its malignant transformation. A detailed report by Labenz et al. in 1997 provided some of the first evidence in support of this theory.²² In a case-control study of 460 duodenal ulcer patients, new-onset GERD symptoms were significantly higher in patients who had successful *H. pylori* eradication than in those with persisting infection. Although a number of subsequent studies have raised doubts as to whether a true relationship exists, the available evidence suggests that the prevalence of *H. pylori* infection in patients with GERD is lower than non-GERD control populations and that there is likely an inverse epidemiologic relationship between GERD and *H. pylori*.

The relationship of Barrett esophagus to gastric *H. pylori* colonization is also debated, although most studies show an even stronger inverse relationship than that of GERD alone. Bowrey et al. reported an *H. pylori* prevalence of 27% in patients with Barrett esophagus compared to 41% in healthy control subjects.²³ Werdmuller and Loffeld also found significantly lower *H. pylori* infection rates in Barrett than non-Barrett patients (23% vs. 51%), whereas Loffeld et al. reported very high rates (62%) in a retrospective analysis of 107 consecutive patients with columnar-lined esophagus.^{24,25} Investigations focused on the role of subpopulations of *H. pylori* have implicated *cagA*⁺ strains as particularly relevant to the development of GE reflux and its complications.²⁶ Vicari et al. demonstrated that in patients with *H. pylori* infection, the prevalence of *cagA*⁺ strains progressively decreased with the severity of GERD, including Barrett esophagus and esophageal adenocarcinoma.²⁷ Other studies have con-

firmed an inverse relationship between the presence of *cagA* positivity and adenocarcinoma of the esophagus and the GE junction.²⁸ Most authors postulate that *cagA*⁺ strains may protect from the development of adenocarcinoma by inducing more severe mucosal inflammation and atrophic gastritis and thereby decreasing acid reflux. Present data regarding gastric acid secretion are conflicting, however, and further studies are required to test whether this hypothesis is true.

Studies on the natural history of GERD are rare. The few that do exist usually involve patients who were receiving some form of therapy. One of the most detailed studies on the natural history of the disease comes from investigators in Europe.²⁹ The progression or regression of GERD complications was assessed in a cohort of nearly 4,000 patients with predominant heartburn over a 2-year period. After 2 years, 25% of patients with nonerosive GERD progressed to erosive disease, 1.6% with mild erosive esophagitis worsened to more severe esophagitis, and nearly 8% progressed to Barrett esophagus, the latter predominantly in patients with Los Angeles grade C/D erosive disease at baseline. On the other hand, 50% to 60% of patients with baseline esophagitis improved to a milder grade or no erosive disease and 22% were off medications at 2 years. Given that virtually all patients were receiving significant antisecretory therapy, the study shows that a substantial minority of patients will continue to worsen despite pharmacologic treatment. Investigators in Lausanne, Switzerland, reported an intensive endoscopic follow-up of a defined population of 959 patients over a 30-year period.³⁰ The study involved only patients who had endoscopic esophagitis and did not include those who had symptoms without mucosal injury. Esophagitis was an isolated episode and did not return while on acid suppression therapy in roughly half of the patients. In the remaining patients, esophagitis intermittently recurred on acid suppression therapy, and in 42% it progressed on therapy to more severe mucosal injury. This latter group makes up roughly one quarter of the initial population of patients with esophagitis, similar to that reported in the Labenz study outlined previously. The study also showed that as many as 18% of the initial population may have acquired, while on therapy, a columnar-lined lower esophagus with intestinal metaplasia.

Clinical Presentation

The most common complaints in patients with GERD are heartburn, regurgitation, and dysphagia or difficulty swallowing. These represent the so-called typical symptoms of GERD. Although none of these are specific to GERD, dysphagia is

FIGURE 41.11. Prevalence of erosive esophagitis in 994 patients with varying severity and frequency of reflux symptoms. (Reproduced with permission from Venables TL, Newland RD, Patel AC, et al. Omeprazole 10 milligrams once daily, omeprazole 20 milligrams once daily, or ranitidine 150 milligrams twice daily, evaluated as initial therapy for the relief of symptoms of gastro-oesophageal reflux disease in general practice. *Scand J Gastroenterol* 1997;32:965.)

more commonly a sign of serious underlying pathology, including esophageal carcinoma, and should always be investigated promptly and thoroughly.

Heartburn is characterized as a substernal “burning” discomfort often radiating from the epigastrium to sternal notch. Occasionally patients will refer to it as “chest pain” rather than heartburn, and the two can be difficult to distinguish. Even the location can be variable with patients occasionally experiencing discomfort in the epigastrium, base of the neck, back, or other areas. Heartburn is typically made worse by “spicy” foods such as tomato sauce, citrus juices, chocolate, coffee, and alcohol. It occurs 1 to 2 hours after eating, often at night, and is relieved by antacids and antisecretory agents such as the over-the-counter histamine-2 blockers. It is well recognized that the severity of symptoms is not necessarily related to the severity of the underlying disease (Fig. 41.11).

Regurgitation is the spontaneous return of gastric contents proximal to the GE junction. Its spontaneous nature distinguishes it from vomiting. The patient often gets a sensation that fluid or food is returning into the esophagus, even if it does not reach as high as the pharynx or mouth. It is typically worse at night in the recumbent position or when lying down after a meal. Patients commonly compensate by not eating late at night or by sleeping partially upright with several pillows or in a chair. This symptom is often less well relieved with antacids and antisecretory agents, although it may change in character from acid to a more “bland” nature.

Dysphagia is present in up to 40% of patients with GERD. It is generally manifested by a sensation of food hanging up in the lower esophagus (esophageal dysphagia) rather than difficulty transferring the bolus from the mouth to the esophageal inlet (oropharyngeal dysphagia). Classically, dysphagia limited to only solid food, with normal passage of liquids, suggests a mechanical disorder such as a large hernia, stricture, or tumor, whereas difficulty with both solids and liquids suggests a functional or motor disorder. It often develops slowly enough that the patient may adjust his or her eating habits and not necessarily notice that it is happening. Thus, a thorough esophageal history includes an assessment of the patient’s dietary history. Questions should be asked regarding the consistency of food that is typically eaten and whether the patient requires liquids with the meal, is the last to finish, has interrupted a social meal, chokes or vomits with eating, or has been admitted on an emergency basis for food impaction. These assessments, in addition to the ability to maintain nutrition, help to quantify the dysphagia and are important in determining the indications for surgical therapy.

Many patients with GE reflux often manifest “atypical” symptoms, such as cough, asthma, hoarseness, and noncardiac

chest pain. Atypical symptoms are the primary complaint in 20% to 25% of patients with GERD and are secondarily present in association with heartburn and regurgitation in many more. It is considerably more difficult to prove a cause-and-effect relationship between atypical symptoms and GE reflux than it is to do so for the typical symptoms. Consequently, the results of surgical therapy have been correspondingly less good. That is not to say that patients with atypical symptoms are not good candidates for antireflux surgery, because many will benefit greatly, but that in these patients it should be applied cautiously. Often a trial of high-dose proton pump inhibitors (PPIs) is helpful. Given atypical symptoms, the outcome of antireflux surgery is optimal in patients with a good response to medical treatment rather than in those who fail to respond.

2 The diagnosis of GERD based on symptoms alone is correct in only approximately two thirds of patients.³¹ This is because these symptoms are not specific for GE reflux and can be caused by other diseases such as achalasia, diffuse spasm, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease. This fact underscores the need for objective diagnosis before the decision is made for surgical treatment.

Physiology of the Antireflux Barrier

The common denominator for virtually all episodes of gastroesophageal reflux, whether physiologic or pathologic, is the loss of the normal gastroesophageal high-pressure zone and the resistance it imposes to the flow of gastric juice from an environment of higher pressure, the stomach, to an environment of lower pressure, the esophagus. This barrier, composed of both anatomic (flap valve and diaphragm) and physiologic (LES) components, acts to prevent reflux during stressed and unstressed conditions. The key determinates of the barrier include:

1. The frequency of swallow- and non-swallow-induced transient relaxations of the LES
2. The structural integrity of the LES
3. Anatomic alterations of the diaphragmatic crura and gastroesophageal flap valve represented by the angle of His

The presence or absence of pathologic esophageal acid exposure (i.e., abnormal 24-hour pH studies) is not only influenced by the degree of barrier loss but also by esophageal and gastric functional characteristics including esophageal clearance, intra-abdominal pressure, and gastric emptying abnormalities.

TABLE 41.1

NORMAL MANOMETRIC VALUES OF THE DISTAL ESOPHAGEAL SPHINCTER IN 50 SUBJECTS

■ PARAMETER	■ MEDIAN VALUE	■ 2.5TH PERCENTILE	■ 97.5TH PERCENTILE
Pressure (mm Hg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

Transient Relaxation of the Lower Esophageal Sphincter

The lower esophageal high-pressure zone is normally present except in two situations: (a) after a swallow, when it momentarily relaxes to allow passage of food into the stomach, and (b) when the fundus is distended with gas, and it is reflexly relaxed to allow venting of the gas (a belch). In 1982, Dodds et al. reported that non-swallow-induced transient relaxations of the lower esophageal sphincter (TLESRs) were a significant mechanism of gastroesophageal reflux in normal individuals and patients with gastroesophageal reflux disease.³² These spontaneous relaxations occurred without pharyngeal contraction, were prolonged (>10 seconds), and, when reflux occurred, were associated with relaxation of the crural diaphragm. Underscoring the importance of the crural diaphragm to barrier integrity, Mital et al. later showed that pharmacologic elimination of lower esophageal sphincter pressure to zero did not result in reflux unless crural diaphragmatic contraction was also absent.³³ Gastric distention, upright posture, and meals high in fat have all been shown to increase the frequency of TLESRs.^{33,34} The latter observations suggest that unfolding of the sphincter may be responsible for the loss of sphincter pressure.

As a result of these findings, TLESRs became commonly accepted as the major mechanism of gastroesophageal reflux regardless of the underlying severity of disease, despite evidence to the contrary. The facts that in over 80% of patients with symptomatic gastroesophageal reflux a hiatal hernia could be identified and that most patients with erosive esophagitis and Barrett esophagus had incompetent lower esophageal sphincter characteristics at rest were largely ignored by many. When these facts are taken into account, particularly in association with the known characteristics of TLESRs, it seems likely that transient relaxations are (a) a physiologic response to gastric distention by food or gas, (b) the mechanism of belching, and (c) responsible for physiologic reflux episodes in individuals with normal lower esophageal sphincter and hiatal anatomy, but not the primary mechanism of gastroesophageal reflux disease. Evidence supporting this has been provided via studies of Van Herwaarden et al., in which ambulatory esophageal manometry and esophageal pH monitoring were performed on patients with and without hiatal hernia.³⁵ Patients with hiatal hernia had greater esophageal acid exposure and more reflux episodes, but the frequency of TLESRs, and the proportion associated with reflux, was similar in both groups. They concluded that excess reflux in patients with GERD and hiatal hernia is caused by a combination of low LES pressure, swallow-induced relaxation, and straining.

Structural Integrity of the Lower Esophageal Sphincter

In humans, a zone of high pressure can be identified at the junction of the esophagus and stomach. This lower esophageal

“sphincter” provides an important component of the barrier between the esophagus and stomach that normally prevents gastric contents from entering the esophagus. It has no anatomic landmarks, but its presence can be identified by a rise in pressure over gastric baseline as a pressure transducer is pulled from the stomach into the esophagus.

There are three characteristics of the lower esophageal sphincter that maintain its resistance or barrier function to intragastric and intra-abdominal pressure challenges. They are its pressure, its overall length, and the length exposed to the positive-pressure environment of the abdomen (Table 41.1). The tonic resistance of the lower esophageal sphincter is a function of both its pressure and the length over which this pressure is exerted.³⁶ The shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to remain competent (Fig. 41.12). Consequently, a short overall sphincter length can nullify a normal sphincter pressure.³⁷ Further, as the stomach fills, the length of the sphincter decreases, rather like the neck of a balloon shortening as the balloon is inflated. If the overall length of the sphincter is abnormally short when the stomach is empty, then with minimal gastric distention there will be insufficient sphincter length for the existing pressure to maintain sphincter competency, and reflux will occur.

The third characteristic of the lower esophageal sphincter is its position, in that a portion of the overall length of the high-pressure zone should be exposed to positive intra-abdominal pressure. During periods of increased intra-abdominal pressure, the resistance of the lower esophageal sphincter would be

FIGURE 41.12. The relationship between the magnitude of pressure in the high-pressure zone measured at the respiratory inversion point and the overall length of the zone to the resistance to the flow of fluid through the zone. Competent, no flow. Incomplete, flow of varied volumes. Note that the shorter the overall length of the high-pressure zone, the higher the pressures must be to maintain sufficient resistance to remain competent.

overcome if the abdominal pressure were not applied equally to the high-pressure zone and stomach. This is akin to sucking on a soft soda straw immersed in a bottle of Coke; the hydrostatic pressure of the fluid and the negative pressure inside the straw due to sucking cause the straw to collapse instead of allowing the liquid to flow up the straw in the direction of the negative pressure. If the abdominal length is inadequate, the sphincter cannot respond to an increase in applied intra-abdominal pressure by collapsing, and reflux is more liable to result. If the high-pressure zone has an abnormal low pressure, a short overall length, or minimal exposure to the abdominal pressure environment in the fasting state, then there is a permanent loss of lower esophageal sphincter resistance and the unhampered reflux of gastric contents into the esophagus throughout the circadian cycle. This is referred to as a *permanently defective sphincter* and is identified by having one or more of the following characteristics: a high-pressure zone with an average pressure of less than 6 mm Hg, an average overall length of 2 cm or less, and an average length exposed to the positive-pressure environment of the abdomen of 1 cm or less.³⁸ Compared with normal subjects, these values are below the 2.5th percentile for each parameter. The most common cause of a permanently defective sphincter is an inadequate abdominal length, most likely a consequence of the development of a hiatal hernia. It is important to note that an inadequate abdominal length or an abnormally short overall length can nullify the efficiency of a sphincter with a normal pressure.

The presence of a permanently defective sphincter has several implications. First, it is commonly associated with esophageal mucosal injury and predicts that the patient's symptoms may be difficult to control with medical therapy.^{39,40} It is now accepted that when the sphincter is permanently defective, it is irreversible, even when the associated esophagitis is healed. The presence of a permanently defective sphincter is commonly associated with reduced esophageal body function,⁴¹ and if the disease is not brought under control, the progressive loss of effective esophageal clearance can lead to severe mucosal injury, repetitive regurgitation, aspiration, and pulmonary failure.

Anatomic Alterations

With the advent of clinical roentgenology, it became evident that a hiatal hernia was a relatively common abnormality although not always accompanied by symptoms. Philip Allison, in his classic treatise published in 1951, suggested that the manifestations of gastroesophageal reflux disease were caused by the presence of a hiatal hernia. For most of the next two decades, hiatal hernia was considered the primary pathophysiologic abnormality leading to GERD. Indeed, the Allison repair, among the first surgical attempts to treat GERD, consisted of a hernia repair only. As techniques of esophageal manometry were developed in the late 1950s and 1960s, allowing identification and study of the lower esophageal sphincter, attention was slowly diverted away from the hernia as the main pathophysiologic abnormality of GERD. In 1971, Cohen and Harris published a study of the contributions of hiatal hernia to lower esophageal sphincter competence in 75 patients, concluding that hiatal hernia had no effect on GE junction competence.⁴² This paper, published in the *New England Journal of Medicine*, and the growing use of esophageal manometry shifted the emphasis away from the hernia almost exclusively toward features of the lower esophageal sphincter as the primary abnormality in symptomatic GERD.

Perhaps serendipitously, studies of the phenomenon of TLESRs identified the diaphragmatic crura as an important factor in preventing reflux during periods of loss of LES pressure.⁴³ In normal subjects, even with absent LES pressure, reflux does not occur without relaxation of the crural

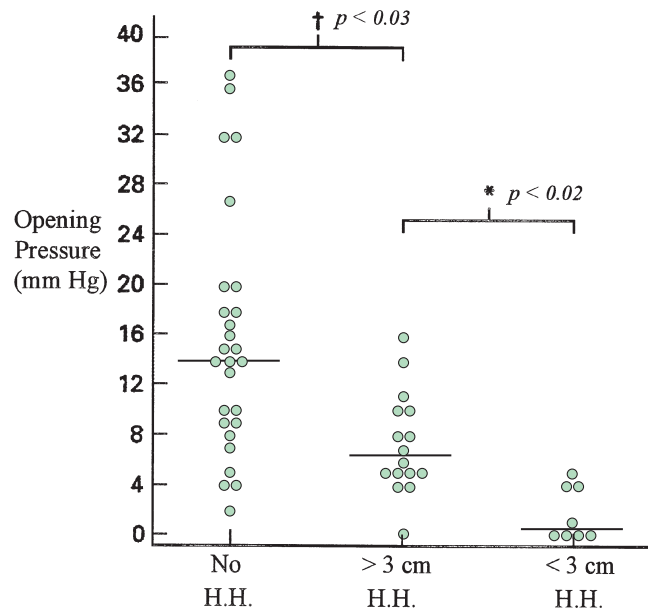

FIGURE 41.13. The intragastric pressure at which the lower esophagus endoscopically opened in response to gastric distention by air during endoscopy. Note that the dome architecture of a hiatal hernia (HH) influences the ease with which the sphincter can be pulled open by gastric distention. (Reproduced with permission from Ismail T, Bancewicz J, Barlow J. Yield pressure, anatomy of the cardia and gastroesophageal reflux. *Br J Surg* 1995;82:943.)

diaphragm. Coincidentally, Hill et al. stressed the importance of the physiologic flap valve created by the angle of His as a barrier to gastroesophageal reflux.⁴⁴ The endoscopic appearance of the flap valve can be correlated with abnormal esophageal acid exposure, emphasizing that the geometry of the gastroesophageal region is also important to barrier competence.⁴⁵ If mechanical forces set in play by gastric distention are important in pulling on the terminal esophagus and shortening the length of the high-pressure zone or “sphincter,” then the geometry of the cardia, that is, the presence of a normal acute angle of His or the abnormal dome architecture of a sliding hiatal hernia, should influence the ease with which the sphincter is pulled open. Evidence that this occurs was provided by Ismail et al., who showed a close relationship between the degree of gastric distention necessary to overcome the high-pressure zone (yield pressure) and the morphology of the cardia (Fig. 41.13).⁴⁶ No relationship between the yield pressure and lower esophageal sphincter resting pressure and length was found. A higher intragastric pressure was needed to open the sphincter in patients with an intact angle of His when compared to patients with a hiatal hernia. The presence of a hiatal hernia also disturbs esophageal clearance mechanisms likely due to loss of anchorage of the esophagus in the abdomen. Kahrilas et al. have shown that complete esophageal emptying was achieved in 86% of swallows in control subjects without a hiatal hernia, 66% in patients with a reducing hiatal hernia, and only 32% of patients with a nonreducing hiatal hernia.⁴⁷ Impaired clearance in patients with nonreducing hiatal hernias further supports the contribution of hiatal hernia to the pathogenesis of gastroesophageal reflux disease. Thus, present evidence is overwhelming that hiatal hernia does indeed play a significant, if not primary, role in the pathophysiology of gastroesophageal reflux disease.

A transient loss of the high-pressure zone can also occur and usually results from a functional problem of the gastric reservoir.⁴⁸ Excessive air swallowing or food can result in gastric dilatation and, if the active relaxation reflex has been lost, an increased intragastric pressure. When the stomach is

distended, the vectors produced by gastric wall tension pull on the GE junction with a force that varies according to the geometry of the cardia; that is, the forces are applied more directly when a hiatal hernia exists than when a proper angle of His is present. The forces pull on the terminal esophagus, causing it to be “taken up” into the stretched fundus and thereby reducing the length of the high-pressure zone or “sphincter.” This process continues until a critical length is reached, usually about 1 to 2 cm, when the pressure drops precipitously and reflux occurs. The mechanism by which gastric distention contributes to shortening of the length of the high-pressure zone, so that its pressure drops and reflux occurs, provides a mechanical explanation for “transient relaxations” of the LES without invoking a neuromuscular reflex. Rather than a “spontaneous” muscular relaxation, there is a mechanical shortening of the high-pressure zone, secondary to progressive gastric distention, to the point where it becomes incompetent. These “transient sphincter” shortenings occur in the initial stages of GERD and are the mechanism for the early complaint of excessive postprandial reflux. After gastric venting, the length of the high-pressure zone is restored and competence returns until distention again shortens it and encourages further venting and reflux. This sequence results in the common complaints of repetitive belching and bloating in patients with GERD. The increased swallowing frequency seen in patients with GERD contributes to gastric distention and is due to their repetitive ingestion of saliva in an effort to neutralize the acid refluxed into their esophagus.⁴⁹ Thus, GERD may begin in the stomach, secondary to gastric distention resulting from overeating and the increased ingestion of fried foods, which delay gastric emptying. Both characteristics are common in Western society and may explain the high prevalence of the disease in the Western world.

A recent series of studies from Glasgow assesses the nature of the acid environment at the GE junction,⁵⁰ including possible inciting factors in the development of cardia and distal esophageal adenocarcinoma. The studies were initiated to investigate a long-recognized observation that esophageal pH monitoring reveals postprandial esophageal acidification at the same time as the gastric contents are alkalinized. This paradox is hard to explain given that reflux of gastric content into the esophagus is the primary mechanism underlying GERD. Hypothesizing that acidic material must be present somewhere in the upper stomach, the investigators studied luminal pH at 1-cm increments across the upper stomach and lower esophagus in healthy volunteers before and after meals. Surprisingly, they identified a “pocket” of acid at the GE junction unaffected by the buffering action of the meal, which extended across the squamocolumnar junction an average of 1.8 cm into the lumen of the esophagus (Fig. 41.14). The authors concluded that this was the source of postprandial esophageal acid exposure. They expanded these initial studies, confirming that the same process occurs in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring 5 cm above the upper border of the LES.⁵¹ Perhaps more important, they also identified that dietary nitrate consumed in the form of green vegetables results in the generation of concentrations of nitric oxide at the GE junction high enough to be potentially mutagenic (Fig. 41.15).⁵² These observations provide the fundamental basis for the observations of inflammation and other alterations in the epithelium long known to occur at the squamocolumnar junction in both overt and unrecognized GERD.

The data support the likelihood that GERD begins in the stomach. Fundic distention occurs because of overeating and delayed gastric emptying secondary to the high-fat Western diet. The distention causes the sphincter to be “taken up” by the expanding fundus, exposing the squamous epithelium with the high-pressure zone, which is the distal 3 cm of the esophagus, to gastric juice. Repeated exposure causes inflammation of the squamous epithelium, columnarization, and carditis.

FIGURE 41.14. Fasting and postprandial gastric and esophageal pH measurements in 1-cm increments during a pull through the gastroesophageal junction. The postprandial tracing reveals an “acid pocket” from 44 to 41 cm from the nares. The fasting tracing reveals this to be the same area as the pH “step-up” corresponding to the transition from the stomach to the esophagus. (Reproduced with permission from Fletcher J, Wirz A, Young J, et al. Unbuffered highly acidic gastric juice exists at the gastroesophageal junction after a meal. *Gastroenterology* 2001;121:775.)

This is the initial step and explains why in early disease the esophagitis is mild and commonly limited to the very distal esophagus. The patient compensates by increased swallowing, allowing saliva to bathe the injured mucosa and alleviate the discomfort induced by exposure to gastric acid. Increased swallowing results in aerophagia, bloating, and repetitive belching. The distention induced by aerophagia leads to further exposure and repetitive injury to the terminal squamous epithelium and the development of cardiac-type mucosa. This is an inflammatory process, commonly referred to as “carditis,” and explains the complaint of epigastric pain so often registered by patients with early disease. The process can lead to a fibrotic mucosal ring at the squamocolumnar junction and explains the origin of a Schatzki ring. Extension of the inflammatory process into the muscularis propria causes a progressive loss in the length and pressure of the distal esophageal high-pressure zone associated with an increased esophageal exposure to gastric juice and the

FIGURE 41.16. Schematic representation of the types of complications of gastroesophageal reflux disease.

symptoms of heartburn and regurgitation. The loss of the barrier occurs in a distal-to-proximal direction and eventually results in the permanent loss of LES resistance and the explosion of the disease into the esophagus with all the clinical manifestations of severe esophagitis. This accounts for the observation that severe esophageal mucosal injury is almost always associated with a permanently defective sphincter. At any time during this process and under specific luminal conditions or stimuli, such as exposure time to a specific pH range, intestinalization of the cardiac-type mucosa can occur and set the stage for malignant degeneration.

Implications

Implications of recognizing anatomic alterations as component of GE barrier:

1. Transient lower esophageal sphincter relaxation is the likely underlying mechanism of belching and physiologic reflux. It does not play a major role in patients with symptomatic gastroesophageal reflux, particularly those with erosive disease, those with Barrett esophagus, or those referred for surgery.
2. Efforts to augment the gastroesophageal barrier either pharmacologically or endoscopically will commonly fail when a hiatal hernia is present.
3. Patients with abnormal esophageal acid exposure in the presence of normal LES characteristics and no hiatal hernia have an uncommon reason for reflux. Gastric or esophageal clearance failure may be present and will seriously complicate postoperative outcome.
4. Both reduction of hiatal hernia and augmentation of the lower esophageal sphincter is necessary to maximally restore gastroesophageal barrier competence.
5. Although acid control without regard to barrier incompetence will improve heartburn and heal esophageal erosive disease, it results in increasing numbers of patients with pulmonary manifestations of GERD.

Complications of Gastroesophageal Reflux Disease

The complications of gastroesophageal reflux result from the damage inflicted by gastric juice on the esophageal mucosa or laryngeal or respiratory epithelium (Fig. 41.16). These can be conceptually divided into (a) mucosal complications such as esophagitis and stricture; (b) extraesophageal or respiratory complications such as chronic cough, asthma, and pulmonary fibrosis; and (c) metaplastic (Barrett esophagus) and neoplastic (adenocarcinoma). The prevalence and severity of complications is related to the degree of loss of the gastroesophageal

barrier, defects in esophageal clearance, and the content of refluxed gastric juice (Fig. 41.17).

Mucosal Complications. The potential injurious components that reflux into the esophagus include gastric secretions, such as acid and pepsin; biliary and pancreatic secretions that regurgitate from the duodenum into the stomach; and toxic compounds generated in the mouth, esophagus, and stomach by the action of bacteria on dietary substances.

Our current understanding of the role of the various ingredients of gastric juice in the development of esophagitis is based on classic animal studies performed by Lillimoe et al.^{53,54} These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Hydrogen ion injury to the esophageal squamous mucosa occurs only at a pH below 2. In acid refluxate, the enzyme pepsin appears to be the major injurious agent. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, while the combination of duodenal juice and gastric acid is particularly noxious. Reflux of bile and pancreatic enzymes into the stomach can either protect or augment esophageal mucosal injury. For instance, the reflux of duodenal contents into the stomach may prevent the development of peptic esophagitis in a patient whose gastric acid secretion maintains an acid environment, because the bile salts would attenuate the injurious effect of pepsin and the acid would inactivate the trypsin. Such a patient would have

FIGURE 41.17. Prevalence of esophageal mucosal injury related to the presence of a defective lower esophageal sphincter, esophageal body motility, or both.

bile-containing acid gastric juice that, when refluxed, would irritate the esophageal mucosa but cause less esophagitis than if it were acid gastric juice containing pepsin. In contrast, the reflux of duodenal contents into the stomach of a patient with limited gastric acid secretion can result in esophagitis, because the alkaline intragastric environment would support optimal trypsin activity and the soluble bile salts with a high pK_a would potentiate the enzyme's effect. Hence, duodenal-gastric reflux and the acid-secretory capacity of the stomach interrelate by altering the pH and enzymatic activity of the refluxed gastric juice to modulate the injurious effects of enzymes on the esophageal mucosa.

This disparity in injury caused by acid and bile alone as opposed to the gross esophagitis caused by pepsin and trypsin provides an explanation for the poor correlation between the symptom of heartburn and endoscopic esophagitis. The reflux of acid gastric juice contaminated with duodenal contents could break the esophageal mucosal barrier, irritate nerve endings in the papillae close to the luminal surface, and cause severe heartburn. Despite the presence of intense heartburn, the bile salts present would inhibit pepsin, the acid pH would inactivate trypsin, and the patient would have little or no gross evidence of esophagitis. In contrast, the patient who refluxed alkaline gastric juice may have minimal heartburn because of the absence of hydrogen ions in the refluxate but have endoscopic esophagitis because of the bile salt potentiation of trypsin activity on the esophageal mucosa. This is supported by recent clinical studies that indicate that the presence of alkaline reflux is associated with the development of mucosal injury.⁵⁵

Although numerous studies have suggested the reflux of duodenal contents into the esophagus in patients with gastroesophageal reflux disease, few have measured this directly. The components of duodenal juice thought to be most damaging are the bile acids, and as such, they have been the most commonly studied. Most studies have implied the presence of bile acids using pH measurements. Studies using either prolonged ambulatory aspiration techniques (Fig. 41.18) or spectrophotometric bilirubin measurement have shown that, as a group, patients with gastroesophageal reflux disease have greater and more concentrated bile acid exposure to the esophageal

mucosa than normal subjects.^{39,40} This increased exposure occurs most commonly during the supine period while asleep and during the upright period following meals. Most studies have identified the glycine conjugates of cholic, deoxycholic, and chenodeoxycholic acids as the predominant bile acids aspirated from the esophagus of patients with GERD, although appreciable amounts of taurine conjugates of these bile acids were also found. Other bile salts were identified but in small concentrations. This is as one would expect because glycine conjugates are three times more prevalent than taurine conjugates in normal human bile.

The potentially injurious action of toxic compounds either ingested or newly formed on the mucosa of the gastroesophageal junction and distal esophagus has long been postulated. Until recently, however, few studies have substantiated this possibility. Expanding upon studies of acid exposure at the gastroesophageal junction, investigators from Glasgow, Scotland, have recently shown that dietary nitrate consumed in the form of green vegetables and food contaminated by nitrate-containing fertilizers results in the generation of nitric oxide at the gastroesophageal junction in concentrations high enough to be potentially mutagenic.⁵² Previous studies have shown that nitrate ingested in food is reabsorbed in the small bowel, with approximately 25% resecreted into the mouth via the salivary glands. Oral bacteria chemically transforms the relatively innocuous nitrate to the more toxic nitrite, which is swallowed and subsequently converted to nitric oxide and other toxic nitroso-compounds by acid and ascorbic acid in the stomach. Whether this mechanism in fact contributes to injury and/or neoplastic transformation in the upper stomach, gastroesophageal junction, and distal esophagus is currently unknown.

4 Respiratory Complications. It is increasingly recognized that a significant proportion of patients with gastroesophageal reflux will have either primary respiratory symptoms or respiratory symptoms in association with more prominent heartburn and regurgitation.⁵⁶ Reflux has been implicated as causative of asthma and idiopathic pulmonary fibrosis (IPF) and can complicate advanced lung diseases including chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF). Thirty-five to fifty percent of asthmatics have been shown to have abnormal esophageal pH, esophagitis, and a hiatal hernia.⁵⁷ Others have shown that the prevalence of reflux symptoms exceeded 50% in patients with asthma and CF.^{58,59} In addition, patients with COPD and gastroesophageal reflux are twice as likely to have significant COPD exacerbations than their nonreflux counterparts,⁶⁰ and reflux symptoms correlate with airway obstruction in COPD patients. These reports suggest that the frequency of dual pathology is higher than would be expected by chance alone.

Pathophysiology of Reflux-induced Respiratory Symptoms. Two mechanisms have been proposed as the pathogenesis of reflux-induced respiratory symptoms. The first, the so-called "reflux" theory, maintains that respiratory symptoms are the result of the aspiration of gastric contents. The second or "reflex" theory maintains that vagally mediated bronchoconstriction follows acidification of the lower esophagus.

The evidence supporting a *reflux* mechanism was shown in animals in the 1950s to 1970s, with studies of acid instillation in the lungs resulting in pneumonitis,^{61,62} epithelial damage,⁶³ and increased airway resistance.⁶⁴ The evidence in humans can be categorized as follows. First, there is radiographic evidence. Patients with pulmonary fibrosis have an increased prevalence of hiatal hernia on upper GI series,^{65,66} while elderly patients with large hiatal hernias have a significantly increased frequency of pleural scarring on chest computed tomography (CT) scans.⁶⁷ Second, erosive esophagitis was found at a high frequency in a large series of Veterans Affairs patients with asthma, pneumonia, chronic bronchitis, and pulmonary fibrosis.⁵⁶ Third, patients with chronic lung diseases, including

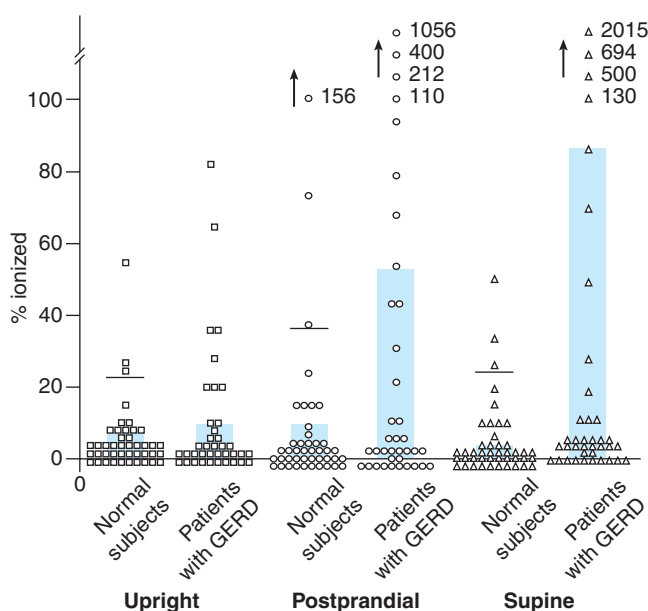

FIGURE 41.18. Peak bile acid concentration ($\mu\text{mol/L}$) for patients and normal subjects during upright, postprandial, and supine aspiration periods. The shaded area represents the mean and the bar the 95th percentile values.

asthma and pulmonary fibrosis in particular, have a significantly higher frequency of positive 24-hour pH studies.^{67,68} With dual pH monitoring of the proximal and distal esophagus, prolonged exposure of the proximal esophagus to gastric juice occurs at a higher frequency in patients with gastroesophageal reflux and respiratory symptoms than in patients without respiratory complaints.^{69,70} Fourth, simultaneous tracheal and esophageal pH monitoring in patients with reflux disease have documented tracheal acidification in concert with esophageal acidification.⁶⁴ Finally, medications used to treat chronic lung diseases, in particular, bronchodilators, relax esophageal sphincter tone.⁷¹

A reflex mechanism is primarily supported by the fact that bronchoconstriction occurs following the infusion of acid into the lower esophagus.⁷²⁻⁷⁴ This can be explained by the common embryologic origin of the tracheoesophageal tract and its shared vagal innervation.

The primary challenge in implementing treatment for reflux-associated respiratory symptoms lies in establishing the diagnosis. In those patients with predominantly typical reflux symptoms and secondary respiratory complaints, the diagnosis may be straightforward. However, in a substantial number of patients with reflux-induced respiratory symptoms, the respiratory symptoms dominate the clinical scenario. Gastroesophageal reflux in these patients is often silent and is only uncovered when investigation is initiated.^{68,75} A high index of suspicion is required, notably in patients with poorly controlled asthma in spite of appropriate bronchodilator therapy. Supportive evidence for the diagnosis can be gleaned from endoscopy and stationary esophageal manometry. Endoscopy may show erosive esophagitis or Barrett esophagus. Manometry may indicate a hypotensive lower esophageal sphincter or ineffective body motility, defined by 30% or more contractions in the distal esophagus of less than 30 mm Hg in amplitude.⁷⁶ D'Ovidio et al. studied 78 patients awaiting lung transplant for IPF, scleroderma, COPD, or CF and found that 72% had a hypotensive lower esophageal sphincter, 33% abnormal esophageal body motility, and 38% abnormal 24-hour pH testing,⁷⁷ although, interestingly, patients with IPF in other series have been shown to have normal manometry.⁷⁰

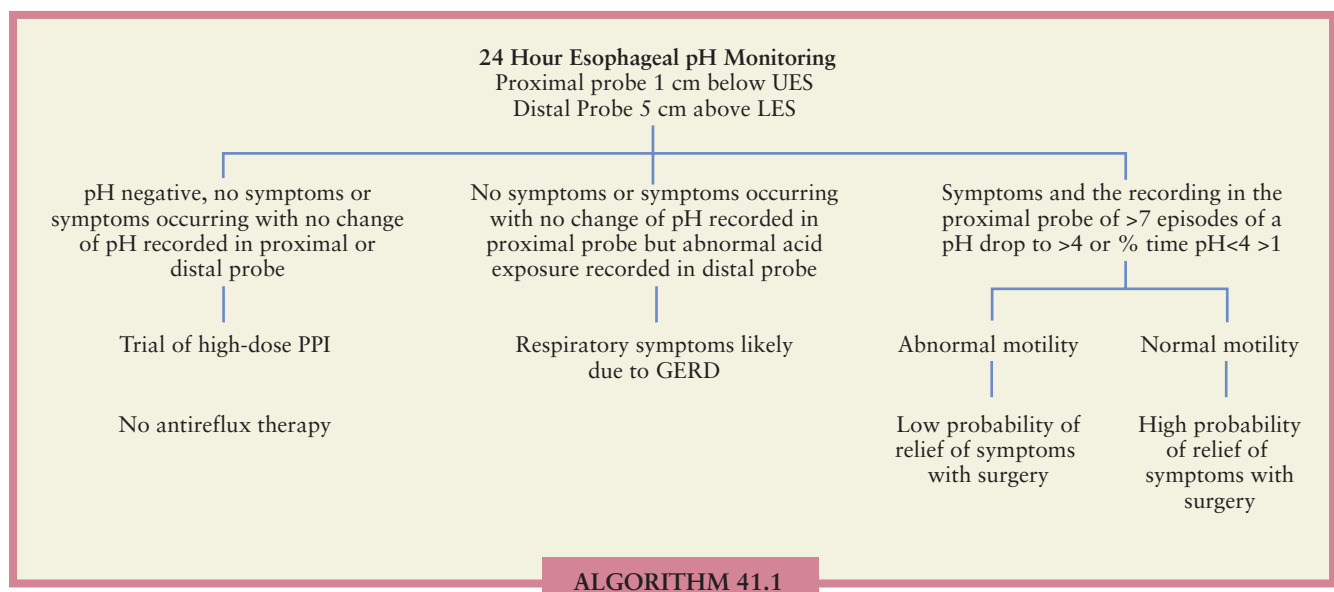

The current "gold standard" for the diagnosis of reflux-induced respiratory complaints is ambulatory dual-probe pH monitoring, often combined with multichannel intraluminal

impedance (MII-pH). One probe is positioned in the distal esophagus and the other at a more proximal location. Sites for proximal probe placement have included the trachea, pharynx, and proximal esophagus. Most authorities would agree that the proximal esophagus is the preferred site for proximal probe placement. While ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and respiratory symptoms, the chronologic relationship between reflux events and bronchoconstriction is complex.

Nonrespiratory Extraesophageal Complications. Other extraesophageal manifestations of gastroesophageal reflux range from laryngitis, pharyngitis, hoarseness, and sinusitis to sleep disturbance and dental erosions.^{78,79} Nearly half of patients referred for antireflux surgery may have nongastrointestinal symptoms. The term *laryngopharyngeal reflux* (LPR) is used for a broad category of atypical symptoms of gastroesophageal reflux, respiratory and nonrespiratory. Mechanisms for these symptoms are difficult to prove and substantial evidence remains lacking.⁸⁰

Treatment of Extraesophageal Complications. Once gastroesophageal reflux is suspected or thought to be responsible for extraesophageal symptoms, treatment may be with either prolonged PPI therapy or antireflux surgery. Initially, a 3- to 6-month trial of high-dose PPI therapy (b.i.d. or t.i.d. dosing) may help confirm (by virtue of symptom resolution) the fact that reflux is partly or completely responsible for the symptoms. If symptoms are improved, patients can be treated with maintenance medical therapy or may be offered surgical treatment to control the reflux. The persistence of symptoms despite PPI treatment, however, does not necessarily rule out reflux as being a potential contributor. Algorithm 41.1 bases clinical decisions on the results of dual-probe 24-hour pH monitoring and is a useful starting point.

Based on reported observations, relief of respiratory symptoms can be anticipated for 25% to 50% of patients with reflux-induced asthma treated with antisecretory medications,⁸¹⁻⁸³ although patients with pulmonary fibrosis in particular may have an inherent resistance to standard-dose PPIs.⁸⁴ Fewer than 15% of asthmatics with symptom relief, however, can be expected to have objective improvements in their pulmonary

ALGORITHM 41.1. Algorithm of clinical decision making based on outcome of dual-probe 24-hour pH testing and esophageal manometry in patients with respiratory symptoms thought secondary to gastroesophageal reflux disease.

function. The reason for this apparent paradox may be that most studies employed relatively short courses of antisecretory therapy (<3 months). This time period may have been sufficient for symptomatic improvement but insufficient for recovery of pulmonary function. The chances of success with medical treatment are likely directly related to the extent of reflux elimination. The conflicting findings of reports of antisecretory therapy may well be due to inadequate control of gastroesophageal reflux in some studies. The literature indicates that antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and reflux disease.^{83,85} Improvements in pulmonary function were demonstrated in around one third of patients. Comparison of the results of uncontrolled studies of each form of therapy and the evidence from the two randomized controlled trials of medical versus surgical therapy indicate that fundoplication is the most effective therapy for reflux-induced asthma.⁸⁵ The superiority of the surgical antireflux barrier over medical therapy is probably most noticeable in the supine posture, which corresponds with the period of acid breakthrough with PPI therapy and is the time in the circadian cycle when asthma symptoms and peak expiratory flow rates are at their worst.

More convincing data establishing the benefit of antireflux surgery in improving respiratory symptoms and pulmonary function tests derives from the lung transplantation literature. Bronchiolitis obliterans syndrome (BOS), synonymous with chronic rejection of the transplanted lung, is diagnosed by a greater than 20% decline in pulmonary function tests from posttransplant baseline. Lau et al. showed in the early 2000s that 67% of 18 patients with BOS had an improvement in their pulmonary function tests after antireflux surgery.⁸⁶ More recently, several groups have reported improvements in oxygen requirements and stabilization of declining pulmonary function tests when pre-lung transplant patients underwent antireflux surgery.^{87,88} In addition, pulmonary and other extraesophageal symptoms can improve after laparoscopic Nissen fundoplication with minimal perioperative morbidity.⁸⁹

It is also important to realize that, in asthmatic patients with a non-reflux-induced motility abnormality of the esophageal body, performing an antireflux operation may not prevent the aspiration of orally regurgitated, swallowed liquid or food. This can result in respiratory symptoms and airway irritation that may elicit an asthmatic reaction. This factor may be the explanation why surgical results appear to be better in children than adults, since disturbance of esophageal body motility is more likely in adult patients.

Metaplastic (Barrett) and Neoplastic (Adenocarcinoma) Complications. The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950 (Fig. 41.19).⁹⁰ He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurring in 7% to 10% of patients with gastroesophageal reflux disease, and represents the end stage of the natural history of this disease.⁹¹ It is also understood to be distinctly different from the congenital condition in which islands of mature gastric columnar epithelium are found in the upper half of the esophagus.

The definition of Barrett esophagus has evolved considerably over the past decade.^{90–93} Traditionally, Barrett esophagus was identified by the presence of any columnar mucosa extending at least 3 cm into the esophagus. Recent data indicating that specialized intestinal-type epithelium is the only tissue predisposed to malignant degeneration, coupled with the finding of a similar risk of malignancy in segments of intestinal metaplasia less than 3 cm long, have resulted in the diagnosis of Barrett esophagus, given any length of endoscopically visible tissue that is intestinal metaplasia on histology (Fig. 41.20). Whether to call long segments of columnar mucosa without intestinal metaplasia Barrett esophagus is unclear. The hall-

FIGURE 41.19. Endoscopic appearance of Barrett esophagus. Note the pink metaplastic mucosa as opposed to the normal whitish squamous lining of the esophagus.

mark of intestinal metaplasia is the presence of goblet cells. Recent studies have identified a high prevalence of biopsy-proven intestinal metaplasia at the cardia, in the absence of endoscopic evidence of a columnar-lined esophagus. The significance and natural history of this finding remain unknown. The term *Barrett esophagus* should currently be used in the setting of an endoscopically visible segment of intestinal metaplasia of any length or columnar replacement of the esophagus of 3 cm or more.

Factors predisposing to the development of Barrett esophagus include early-onset GERD, abnormal lower esophageal sphincter and esophageal body physiology, and mixed reflux of gastric and duodenal contents into the esophagus.⁹³ Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58% of the patients with gastroesophageal reflux disease have increased esophageal exposure to duodenal juice and that this exposure is most dramatically related to Barrett esophagus.⁹⁴

FIGURE 41.20. Histologic appearance of Barrett esophagus. To the left of the photograph, columnar mucosa with abundant goblet cells is seen. This is intestinal metaplasia, which is the histologic hallmark of Barrett esophagus. To the right of the photomicrograph, cardiac epithelium is present.

Pathophysiology of Barrett Metaplasia. Recent studies suggest that the metaplastic process at the gastroesophageal junction may begin by conversion of distal esophageal squamous mucosa to cardiac-type epithelium, heretofore presumed to be a normal finding.⁹² This is likely due to exposure of the distal esophagus to excess acid and gastric contents via prolapse of esophageal squamous mucosa into the gastric environment. This results in inflammatory changes at the gastroesophageal junction and/or a metaplastic process, both of which may result in the loss of muscle function and a mechanically defective sphincter allowing free reflux with progressively higher degrees of mucosal injury. Intestinal metaplasia within the sphincter may result, as in Barrett metaplasia of the esophageal body. This mechanism is supported by the finding that as the severity of gastroesophageal reflux disease progresses, the length of columnar lining above the anatomic gastroesophageal junction is increased.

Treatment. The relief of symptoms remains the primary force driving antireflux surgery in patients with Barrett esophagus. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with Barrett esophagus are no different than the broader population of patients with gastroesophageal reflux. Antireflux surgery should be considered when patient factors suggest severe disease or predict the need for long-term medical management, both of which are almost always true in patients with Barrett esophagus.

7 PPI therapy, both to relieve symptoms and to control any coexistent esophagitis or stricture, is an acceptable treatment option in patients with Barrett esophagus. Once initiated, however, most patients with Barrett esophagus will require life-long treatment. Complete control of reflux with PPI therapy can be difficult, however, as has been highlighted by studies of acid breakthrough while on therapy. Katzka and Castell, and Ouatu-Lascar and Triadafilopoulos have shown that 40% to 80% of patients with Barrett esophagus continue to experience abnormal esophageal acid exposure despite up to 20 mg twice daily of PPI.^{95,96} Ablation trials have shown that mean doses of 56 mg of omeprazole are necessary to normalize 24-hour esophageal pH studies.⁹⁷ Antireflux surgery likely results in more reproducible and reliable elimination of reflux of both acid and duodenal content, although long-term outcome studies suggest that as many as 25% of patients postfundoplication will have persistent pathologic esophageal acid exposure confirmed by 24-hour pH studies.⁹⁸

An important consideration is that patients with Barrett esophagus generally have severe GERD, with its attendant sequelae such as large hiatal hernia, stricture, shortened esophagus, and poor motility. Compared to mild and nonerosive reflux disease, severe erosive disease and Barrett esophagus are associated with significantly greater loss of the mechanical antireflux barrier because of associated hiatal hernias and a hypotensive lower esophageal sphincter. Surgical treatment with a laparoscopic Nissen fundoplication reduces the hiatal hernia, improves the antireflux barrier, and consequently provides similarly excellent symptom control.⁹⁹ Large studies in patients with typical acid reflux symptoms have been published from the United States and Europe.^{100–103} In patients having laparoscopic Nissen fundoplication at Emory University, relief of heartburn and regurgitation occurred in 90%, and 70% were off all reflux medications at a mean follow-up of 11 years.¹⁰⁴ These results emphasize the durability of the procedure as well as the persistent relief of typical symptoms. Risk factors for persistent use of antacids after antireflux surgery include a partial fundoplication, older age, and female gender.¹⁰⁵

Studies focusing on the symptomatic outcome following antireflux surgery in patients with Barrett esophagus document excellent to good results in 72% to 95% of patients at 5 years following surgery.^{98–100} The outcome of laparoscopic Nissen fundoplication in patients with Barrett esophagus has

been assessed at 1 to 3 years after surgery. Hofstetter et al. reported the experience at the University of Southern California (USC) in 85 patients with Barrett esophagus at a median of 5 years after surgery. Fifty-nine had long- and 26 short-segment Barrett esophagus and 50 underwent a laparoscopic antireflux procedure.⁹⁸ Reflux symptoms were absent postoperatively in 79% of the patients. Postoperative 24-hour pH was normal in 17 of 21 patients (81%). Ninety-nine percent of the patients considered themselves cured or improved and 97% were satisfied with the surgery. In addition to symptomatic improvement in reflux after surgery, there is evidence that mediators of esophageal inflammation implicated in carcinogenesis are decreased as well. Cyclooxygenase-2 (COX-2) gene expression is elevated in the distal esophagus of reflux patients, but the expression of COX-2 and another inflammatory mediator, interleukin 8, can be decreased in the distal esophageal mucosa after a fundoplication.^{106–108}

The Development of Dysplasia in Barrett Esophagus. The prevalence of dysplasia at diagnosis in patients presenting with Barrett esophagus ranges from 15% to 25%, and approximately 5% of patients will develop dysplasia each year. The identification of dysplasia in Barrett epithelium rests on histologic examination of biopsy specimens. The cytologic and tissue architectural changes are similar to those described in ulcerative colitis (Fig. 41.21). By convention, Barrett metaplasia is currently classified into four broad categories:

1. No dysplasia
2. Indefinite for dysplasia
3. Low-grade dysplasia
4. High-grade dysplasia

8 There are few prospective studies documenting the progression of nondysplastic Barrett epithelium to low- or high-grade dysplasia. Those that are available suggest that 5% to 6% per year will progress to dysplasia and 0.5% to 1% per year to adenocarcinoma (Table 41.2). Once identified, Barrett esophagus complicated by dysplasia should undergo aggressive therapy. Patients whose biopsies are interpreted as indefinite for dysplasia should be treated with a medical regimen consisting of 60 to 80 mg of PPI therapy for 3 months and rebiopsied. Importantly, esophagitis should be healed prior to interpretation of the presence or absence of dysplasia. The presence of severe inflammation makes the microscopic interpretation of dysplasia difficult. The purpose of acid suppression therapy is to resolve inflammation that may complicate the interpretation of the biopsy specimen. If the

diagnosis remains indefinite, the patient should be treated as if low-grade dysplasia were present with continued medical therapy or antireflux surgery and repeat biopsy every 6 months.

- 9 High-grade dysplasia should be confirmed by two pathologists knowledgeable in GI pathology. Once high-grade dysplasia is confirmed, observation is less than optimal as more than 50% of patients will progress to multifocal high-grade dysplasia or cancer.¹⁰⁹ Until recently, esophagectomy was considered the standard of care for patients with high grade dysplasia. With the Western acceptance of an Eastern modality, endoscopic mucosal resection (EMR) is becoming an increasingly attractive option for patients with high-grade dysplasia and intramucosal cancers. The aim of EMR is to excise the area of interest including the mucosal and submucosal layers down to the lamina muscularis propria allowing optimal histologic interpretation. Reports from specialized centers combining EMR with mucosal ablation using either photodynamic or radiofrequency energy are encouraging, with a high prevalence of eradication of dysplasia/neoplasia.^{110–115} Ell et al. initially showed that EMR is feasible and safe; however, in one of their earlier reports, recurrent or metachronous carcinomas were found in 14% of 64 patients during 1-year follow-up.¹¹⁶

Longer success rates with EMR for early Barrett cancer have been reported from the experienced centers. The largest study comes from Wiesbaden, Germany, involving over 300 patients with high-grade dysplasia or intramucosal cancers and a mean follow-up of over 5 years.¹¹⁷ A complete response was achieved in 97% of patients, and surgery was necessary in 3.7% after endoscopic therapy failed. Metachronous lesions developed during the follow-up in 21% of the patients. The risk factors most frequently associated with recurrence were piecemeal resection, long-segment Barrett esophagus, and multifocal lesions.¹¹⁸

- 10 Traditionally, high-grade dysplasia has been considered a marker for the presence of invasive carcinoma in nearly half of patients, as confirmed in esophagectomy reports from the University of Southern California, Mayo Clinic, Johns Hopkins, and other centers.^{119–122} It is not possible with present technology, including endoscopic ultrasound, to differentiate the patients who harbor a cancer from those who do not. Furthermore, esophageal adenocarcinoma associated with high-grade dysplasia, identified by surveillance endoscopy, is generally highly curable. We and others have documented 5-year survival rates of 90% after potentially curative esophagectomy. Although on average 30% to 40% of patients with the preoperative diagnosis of high-grade dysplasia will harbor invasive cancer when the esophagus is examined in its entirety, removal of the lesion via EMR, histologic assessment including the submucosa, and the addition of mucosal ablation of residual Barrett epithelium are shifting the treatment paradigm. How-

ever, the standard of care for treatment of high-grade dysplasia and intramucosal carcinoma outside a specialized esophageal center, particularly in younger patients or those unable to undergo consistent endoscopic surveillance, remains esophagectomy.

Treatment of Gastroesophageal Reflux Disease

Medical Treatment. GERD is one of the most prevalent conditions encountered in general medical practice. As a result, medications for control of GERD comprise one of the largest pharmaceutical markets in the United States and abroad. Since PPIs were introduced in the United States in 1989, a number of different agents have emerged, each with substantial penetration in the marketplace. Data from the year 2004 reveal that, of the top 10 expenditures for medications in the United States, the third highest dollar amount was spent on Prevacid (lansoprazole, TAP Pharmaceutical Products, Inc., Lake Forest, Illinois; \$4.0 billion), while the fourth highest was on Nexium (esomeprazole magnesium, AstraZeneca Pharmaceuticals, Wilmington, Delaware; \$3.6 billion).^{123,124}

GERD is such a common condition that most patients with mild symptoms carry out self-medication, particularly now that generic and over-the-counter H₂-receptor antagonists (H₂RAs) and PPIs have become widely available. When first seen with symptoms of heartburn or regurgitation without obvious complications, patients can reasonably be placed on 8 to 12 weeks of acid suppression therapy before extensive investigations are carried out. In many situations, symptoms successfully resolve. Patients should be advised to elevate the head of the bed; avoid tight clothing; eat small, frequent meals; avoid eating their nighttime meal shortly before retiring; lose weight; and avoid alcohol, coffee, chocolate, and peppermints, which may aggravate the symptoms. Medications to promote gastric emptying, such as metoclopramide, are beneficial in early disease but of little value in more severe disease.

- 11 The mainstay of maintenance medical therapy is acid suppression. Patients with persistent symptoms should be given PPIs, such as omeprazole. In doses as high as 40 mg/d, they can effect an 80% to 90% reduction in gastric acidity. Such a regimen usually heals mild esophagitis, but healing may occur in only three fourths of patients with severe esophagitis. It is important to realize that in patients who reflux a combination of gastric and duodenal juice, inadequate acid suppression therapy may give symptomatic improvement while still allowing mixed reflux to occur. This can result in an environment that allows persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.¹²⁵

In patients with reflux disease, esophageal acid exposure is reduced by up to 80% with H₂RAs and up to 95% with PPIs. Despite the superiority of the latter class of drug over the former, periods of acid breakthrough still occur.^{126,127} Breakthrough occurs most commonly at nighttime and is some justification for a split rather than a single dosing regimen. Katzka et al.¹²⁶ studied 45 patients with breakthrough reflux symptoms while on omeprazole 20 mg b.i.d. and found that 36 patients were still refluxing, defined by a total distal esophageal acid exposure greater than 1.6%. Peghini et al.¹²⁷ employed intragastric pH monitoring in 28 healthy volunteers and 17 patients with reflux disease and found that nocturnal recovery of acid secretion (more than 1 hour) occurred in 75% of the individuals. Recovery of acid secretion occurred within 12 hours of the oral evening dose of PPI, the median recovery time being 7.5 hours. This is particularly pertinent because it is during the nighttime and early morning that asthma symptoms are most pronounced and that peak expiratory flow rate is at its lowest. Ranitidine 300 mg at bedtime appears superior to omeprazole 20 mg at bedtime in preventing acid breakthrough, likely due to the abolition of histamine-mediated acid secretion in the fasting state.

An accumulating body of literature suggests potential adverse consequences to long-term acid suppressive therapy. A population-based cohort study from the Netherlands covering the years 1995–2002 revealed higher incidence rates of community-acquired pneumonia in patients using H₂RAs or PPIs compared to those who never used them or those who had used them previously but stopped.¹²⁸ The risk was most pronounced for PPIs and showed a clear dose-response relationship. Other studies have focused on the association between acid suppression and the development of osteoporosis-related fractures.^{129–131} Of note, a population-based study from the United Kingdom assessed the risk of hip fractures from long-term PPI therapy.¹²⁹ The study covered the years 1987–2003 and compared users of PPI therapy to nonusers of any acid suppressive medication. The risk of hip fracture was significantly increased in patients prescribed long-term high-dose PPI, and the strength of the association increased with increasing duration of PPI therapy. The authors conjectured that calcium malabsorption secondary to chronic acid suppression may potentially explain the positive association.

Failure of acid suppression to control symptoms or immediate return of symptoms after stopping treatment suggests that either the diagnosis is incorrect or the patient has relatively severe disease. Endoscopic examination at this stage of the patient's evaluation provides the opportunity for assessing the severity of mucosal damage and the presence of Barrett esophagus. Both of these findings on initial endoscopy predict a high risk for medical failure. A measurement of the degree and pattern of esophageal exposure to gastric juice, with 24-hour pH monitoring, should be obtained at this point. The status of the LES and the function of the esophageal body should also be assessed. These studies identify features that predict a poor response to medical therapy, frequent relapses, and the development of complications and include supine reflux, poor esophageal contractility, erosive esophagitis, a columnar-lined esophagus, and a structurally defective sphincter. Patients who have these risk factors should be given the option of surgery as a primary therapy with the expectation of long-term control of symptoms and complications.

Antireflux Surgery

Indications. Antireflux surgery is indicated for the treatment of objectively documented, relatively severe GERD. Candidates for surgery include not only patients with erosive esophagitis, stricture, and Barrett esophagus but also those without severe mucosal injury who are dependent on PPIs for symptom relief. Patients with atypical or respiratory symptoms who have a good response to intensive medical treatment are also candidates. The option of antireflux surgery should be given to all

patients who have demonstrated the need for long-term medical therapy, particularly if escalating doses of PPIs are needed to control symptoms. Antireflux surgery may be the preferred option in patients younger than 50 years, those who are non-compliant with their drug regimen, those for whom medications are a financial burden, and those who favor a single intervention over long-term drug treatment. It may be the treatment of choice in patients who are at high risk of progression despite medical therapy. Although this population is not well defined, risk factors that predict progressive disease and a poor response to medical therapy include (a) nocturnal reflux on 24-hour esophageal pH study, (b) a structurally deficient LES, (c) mixed reflux of gastric and duodenal juice, and (d) mucosal injury at presentation.¹³²

Preoperative Evaluation. Successful antireflux surgery is largely defined by two objectives: the achievement of long-term relief of reflux symptoms and the absence of complications or complaints after the operation. In practice, achieving these two deceptively simple goals is difficult. Both are critically dependent on establishing that the symptoms for which the operation is performed are the result of excess esophageal exposure to gastric juice, as well as the proper performance of the appropriate antireflux procedure. Success can be expected in the vast majority of patients if these two criteria are met. The status of the LES is not as important a factor as in the days of open surgery. Patients with normal resting sphincters are often selected for antireflux surgery in the era of laparoscopic fundoplication. The outcome is not dependent on sphincter function. There are four important goals of the diagnostic approach to patients suspected of having GERD and being considered for antireflux surgery (Table 41.3).

The introduction of laparoscopic access, coupled with the growing recognition that surgery is a safe and durable treatment for GERD, has dramatically increased the number of patients being referred for laparoscopic fundoplication compared to the prelaparoscopic era. Recent data suggest that the peak use of antireflux surgery in the United States occurred in 1999, with an estimated 15.7 cases per 100,000 adults at that time.¹³³ Since then, the frequency of antireflux surgery has declined, such that an estimated 11 antireflux procedures were performed per 100,000 adults in 2003. This recent decline may reflect the availability of generic and over-the-counter PPIs, a constantly evolving menu of endoscopic antireflux therapies, increased utilization of Roux-en-Y gastric bypass for control of GERD in morbidly obese individuals, and the long-term efficacy of fundoplication being called into question. Given the various therapies for GERD, each with its potential advantages and shortcomings, accurate and contemporary data regarding outcomes after antireflux surgery are necessary as a basis against which other established and novel therapies must be judged.

TABLE 41.3

DIAGNOSIS

GOALS OF THE DIAGNOSTIC APPROACH TO PATIENTS SUSPECTED OF HAVING GERD AND BEING CONSIDERED FOR ANTIREFLUX SURGERY

Establish that GERD is the underlying cause of the patient's symptoms.

Estimate the risk of progressive disease.

Determine the presence or absence of esophageal shortening.

Evaluate esophageal body function and, occasionally, gastric emptying function.

GERD, gastroesophageal reflux disease.

TABLE 41.4

PREDICTORS OF OUTCOME AFTER LAPAROSCOPIC FUNDOPLICATION: STEPWISE LOGISTIC REGRESSION RESULTS OF 199 PATIENTS

Odds ratios and corresponding *p* values are adjusted for age and for all other factors in the model.

From Campos GMR, Peters JH, DeMeester TR, et al. Multivariate analysis of the factors predicting outcome after laparoscopic Nissen fundoplication. *J Gastrointest Surg* 1999;3:292–300.

Given the large number of surgical referrals, the importance of selecting patients for surgery who are likely to have a successful outcome cannot be overemphasized. Although a Nissen fundoplication will reliably and reproducibly halt the return of gastroduodenal juice into the esophagus, little benefit is likely if the patient's symptoms are not caused by this specific pathophysiologic derangement. Thus, in large part, the anticipated success rate of laparoscopic fundoplication is directly proportional to the degree of certainty that GERD is the underlying cause of the patient's complaints.

- 12 Three factors predictive of a successful outcome following antireflux surgery have emerged (Table 41.4).¹³⁴ These are (a) an abnormal score on 24-hour esophageal pH monitoring; (b) the presence of typical symptoms of GERD, namely, heartburn or regurgitation; and (c) symptomatic improvement in response to acid suppression therapy prior to surgery. It is immediately evident that each of these factors helps to establish that GERD is indeed the cause of the patient's symptoms and that they have little to do with the severity of the disease.

Endoscopic Assessment. Endoscopic visualization of the esophagus equates to the physical examination of the foregut and is a critical part of the preoperative evaluation of patients with GERD. Its main aim is to detect complications of GE reflux, the presence of which may influence therapeutic decisions.

In every patient, the locations of the diaphragmatic crura, the GE junction, and the squamocolumnar junction are determined. These anatomic landmarks are commonly at three different sites in patients with GERD. The crura are usually evident and can be confirmed by having the patient sniff during the examination. The anatomic GE junction is identified as the point where the gastric rugal folds meet the tubular esophagus and is often below the squamocolumnar junction, even in patients without otherwise obvious Barrett esophagus.

Endoscopic esophagitis is defined by the presence of mucosal erosions (Table 41.5). When present, the grade and length of esophageal mucosal injury are recorded. The presence and length of columnar epithelium extending above the anatomic GE junction is also noted. Columnar-lined esophagus (CLE) is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location and by the appearance of a velvety red luxuriant mucosa. The presence of Barrett esophagus is confirmed by biopsy evidence of specialized intestinal metaplasia involving the tubular esophagus and is considered histologic evidence of GERD. Endoscopic visualization of columnar lining without histologic confirmation of specialized intestinal metaplasia is not considered

Barrett esophagus and likely has no premalignant potential. Multiple biopsies should be taken in a cephalad direction to determine the level at which the junction of Barrett epithelium and normal squamous mucosa occurs. Barrett esophagus is susceptible to ulceration, bleeding, stricture formation, and malignant degeneration. Dysplasia is the earliest sign of malignant change. Because dysplastic changes typically occur in a random distribution within the distal esophagus, a minimum of four biopsies (each quadrant) every 2 cm should be obtained from the metaplastic epithelium. Particular attention must be paid to the squamocolumnar junction in these patients, where a mass, ulcer, nodularity, or inflammatory tissue is always considered suspicious for malignancy and requires thorough biopsy or endoscopic resection. The GE junction is defined endoscopically where the tubular esophagus meets gastric rugal folds, and the squamocolumnar junction is where there is an obvious change from the velvety and darker columnar epithelium to the lighter squamous epithelium.

After completion of the esophageal examination, the first and second portions of the duodenum and the stomach are systematically inspected. This is commonly done on withdrawal of the endoscope. When the antrum is visualized, the incisura angularis appears as a constant ridge on the lesser curve. Turning the lens of the scope 180 degrees allows inspection of the fundus and cardia. Attention is paid to the frenulum (angle of His) of the esophagogastric junction and to the closeness with which the cardia grips the scope. Hill et al.¹³⁵ have graded the appearance of this valve on a scale from I to IV according to the

TABLE 41.5**CLASSIFICATION**

MODIFIED LOS ANGELES CLASSIFICATION OF ESOPHAGITIS

GRADE	LESION
A	One (or more) mucosal break of longer than 5 mm that does not extend between the tops of two mucosal folds
B	One (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds
C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but that involves <75% of the circumference
D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

degree of unfolding or deterioration of the normal valve architecture. This grading system has been correlated with the presence of increased esophageal acid exposure, occurring predominantly in patients with a grade III or IV valve.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura. A prominent sliding hernia is frequently associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia exists, particular attention is given to exclude a gastric ulcer or gastritis within the pouch. The term *Cameron erosions* refers to such mucosal erosions occurring in large sliding or paraesophageal hernias, typically at the level of the diaphragmatic hiatus. The intragastric retroflex or “J” maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach. As the endoscope is removed, the esophagus is again examined and biopsies taken. The location of the cricopharyngeus is identified and the larynx and vocal cords are visualized. Acid reflux may result in inflammation of the larynx. Vocal cord movement is recorded both as a reference for subsequent surgery and an assessment of the patient's ability to protect the airway.

Twenty-four Hour Ambulatory pH Monitoring. The most direct method of assessing the relationship between symptoms and GERD is to measure the esophageal exposure to gastric juice with an indwelling pH electrode. Miller¹³⁶ first reported prolonged esophageal pH monitoring in 1964, although it was not until 1973 that its clinical applicability and advantages were demonstrated by Johnson and DeMeester.¹³⁷ Ambulatory pH testing is considered by many to be the “gold standard” for the diagnosis of GERD, because it has the highest sensitivity and specificity of all tests currently available. Some experts have suggested that 24-hour pH monitoring be used selectively, limited to patients with atypical symptoms or no endoscopic evidence of GE reflux. Given present-day referral patterns, more than half of the patients referred for antireflux surgery will have no endoscopic evidence of mucosal injury. For these patients, 24-hour pH monitoring provides the only objective measure of the presence of pathologic esophageal acid exposure. Although it is true that most patients with typical symptoms and erosive esophagitis have a positive 24-hour pH result, the pH study provides other useful information. It quantifies the actual time that the esophageal mucosa is exposed to gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient's symptoms. It is the only way to quantitatively express the overall degree and pattern of esophageal acid exposure, both of which may impact the decision toward surgery.¹³⁸ Patients with nocturnal or bipositional reflux have a higher prevalence of complications and failure of long-term

medical control. For these reasons, we continue to advocate the routine use of pH monitoring in clinical practice.

Present technology includes both transnasal catheter-based pH probes and an implantable capsule (Bravo pH system, Medtronic Corporation, Minneapolis, Minnesota) placed under endoscopic guidance.^{138–140} The units used to express esophageal exposure to gastric juice are (a) cumulative time the esophageal pH is below a chosen threshold, expressed as the percent of the total, upright, and supine monitored time; (b) frequency of reflux episodes above a chosen threshold, expressed as number of episodes per 24 hours; and (c) duration of the episodes, expressed as the number of episodes greater than 5 minutes per 24 hours and the time in minutes of the longest episode recorded. Table 41.6 shows the normal values for these components of the 24-hour record at the whole number pH threshold derived from 50 normal, asymptomatic subjects. The upper limits of normal were established at the 95th percentile. Most centers use pH 4 as the threshold. Combining the result of the six components into one expression that reflects the overall esophageal acid exposure below a pH threshold, a pH score was calculated by using the standard deviation of the mean of each of the six components measured.

Several limitations exist, however, to standard pH monitoring: nonacid reflux events are not detected, the height and quantity of refluxate above the gastroesophageal junction are not defined, and the physical nature of the refluxed material (i.e., liquid, gas, or a mixture) cannot be differentiated. As reflux symptoms such as regurgitation and cough may be present in the absence of demonstrable reflux of acid, improved modalities for detection of nonacid refluxate may be clinically important.

Ambulatory Combined Impedance-pH Monitoring. New technology has been introduced into clinical practice that allows for detection of both acid and nonacid refluxate. The Sleuth system (Sandhill Scientific, Denver, Colorado) combines pH monitoring and intraluminal impedance measurements using a single catheter (Fig. 41.22). The technology identifies refluxate via changes in impedance caused by the presence of a bolus in the esophagus, and the reflux event can be categorized as acid or nonacid by the contemporaneous change in intraluminal pH. Multichannel intraluminal impedance (MII) has been validated as an appropriate method for the evaluation of gastrointestinal function and reflux.¹⁴¹ All episodes of gastroesophageal reflux can be detected using this technology without regard to their chemical composition. Surprisingly, recent studies using this technology have shown that, in normal subjects, PPI therapy does not alter the number of reflux episodes; it simply converts them to neutral pH.¹⁴² This observation may have important implications in the treatment of gastroesophageal reflux disease.

TABLE 41.6

NORMAL VALUES FOR ESOPHAGEAL EXPOSURE TO pH <4 IN 50 SUBJECTS

■ COMPONENT	■ MEAN	■ STANDARD DEVIATION	■ 95TH PERCENTILE
Total time pH <4	1.51	1.36	4.45
Upright time pH <4	2.34	2.34	8.42
Supine time pH <4	0.63	1.0	3.45
No. episodes	19.00	12.76	46.9
No. >5 min	0.84	1.18	3.45
Longest episode	6.74	7.85	19.8

FIGURE 41.22. Combined multichannel intraluminal impedance-pH catheter. (Reproduced with permission from Mainie I, Tutuian R, Agrawal A, et al. Combined multichannel intraluminal impedance-pH monitoring to select patients with persistent gastro-oesophageal reflux for laparoscopic Nissen fundoplication. *Br J Surg* 2006;93:1483–1487.)

Combined MII-pH monitoring has recently been used to select patients, both with typical and atypical manifestations of GERD and who are resistant to medical treatment, for fundoplication.¹⁴³ Patients with a positive symptom index, as assessed by combined MII-pH testing while on PPI therapy, were noted to respond well to surgery. Another recent trial demonstrated that combined MII-pH testing is more accurate for the preoperative assessment of GERD in patients off of PPI therapy compared to pH monitoring alone.¹⁴⁴

Assessment of Esophageal Length. Esophageal shortening is a consequence of scarring and fibrosis associated with repetitive esophageal injury. Anatomic shortening of the esophagus can compromise the ability to perform an adequate tension-free fundoplication and may result in an increased incidence of breakdown or thoracic displacement of the repair. Esophageal length is best assessed preoperatively using video roentgenographic contrast studies and endoscopic findings. Endoscopically, hernia size is measured as the difference between the diaphragmatic crura, identified by having the patient sniff, and the GE junction, identified as the loss of gastric rugal folds. We consider the possibility of a short esophagus in patients with strictures or those with large hiatal hernias (>5 cm), particularly when the latter fail to reduce in the upright position on a video barium esophagram.¹⁴⁵

The definitive determination of esophageal shortening is made intraoperatively when, after thorough mobilization of the esophagus, the GE junction cannot be reduced below the diaphragmatic hiatus without undue tension on the esophageal body. Surgeons performing fundoplication have reported varying incidences of esophageal shortening, attesting to the judgment inherent in defining and recognizing “undue tension.” An advantage of transthoracic fundoplication is the ability to mobilize the esophagus extensively from the diaphragmatic hiatus to the aortic arch. With the GE junction marked with a suture, esophageal shortening is defined by an inability to position the repair beneath the diaphragm without tension. In this situation, a Collis gastroplasty coupled with either a partial or complete fundoplication may be performed.¹⁴⁶

Potential pitfalls of laparoscopic fundoplication include the elevation of the diaphragm due to pneumoperitoneum, potentially contributing to a false impression that esophageal length is adequate, and the limited ability to mobilize the esophagus relative to the transthoracic approach.¹⁴⁷ In our experience, the

failure to appreciate esophageal shortening is a major cause of fundoplication failure and is often the explanation for the “slipped” Nissen fundoplication. In many such instances, the initial repair is incorrectly constructed around the proximal tubularized stomach rather than the terminal esophagus. Surgeons opting to perform fundoplication laparoscopically in the setting of potential esophageal shortening must be vigilant of esophageal tension, technically facile at extensive mediastinal mobilization of the esophagus while preserving vagal integrity, and able to perform a laparoscopic or open transabdominal Collis gastroplasty should esophageal lengthening be necessary.

Radiographic Evaluation. Radiographic assessment of the anatomy and function of the esophagus and stomach is one of the most important parts of the preoperative evaluation. Critical issues are assessed, including the presence of esophageal shortening (Fig. 41.23), the size and reducibility of a hiatal hernia, and the propulsive function of the esophagus for both liquids and solids.

The definition of radiographic GE reflux varies depending on whether reflux is spontaneous or induced by various maneuvers. In only about 40% of patients with classic symptoms of GERD is spontaneous reflux observed by the radiologist (i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position). In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-hour esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. On the contrary, failure to see radiographic reflux does not prove the absence of reflux disease.

A carefully performed video esophagram can provide an enormous amount of information on the structure and function of the esophagus and stomach. The modern barium

TABLE 41.7

DIAGNOSIS

UNIVERSITY OF SOUTHERN CALIFORNIA PROTOCOL FOR VIDEO ESOPHAGRAM STUDIES

PATIENT POSITION	PURPOSE	TECHNIQUE
Prone RAO	Esophageal body function	Five separate 10-mL swallows, 15 s between each, follow bolus on videotape
	Esophageal diameter	Video swallow over thoracic inlet and another over distal third of esophagus without panning
	Gastric function	Rapid swallow of several gulps to distend esophagus maximally Video-record activity of stomach and duodenum for 30 s in prone position
Supine	Relationship of GE junction to hiatus	Two or three individual swallows focused on distal esophagus and GE junction
Erect	Cricopharyngeal function	Lateral and anteroposterior views of oropharynx and upper esophagus
	Mucosal injury	Spot of collapsed esophagus for mucosal detail
	Reducibility of hernia	Video images of one or two swallows focused on distal esophagus and GE junction
Erect	Gas distention of distal esophagus	
	Solid bolus transport	Record video images of passage of two contrast-coated hamburger boluses from oropharynx to stomach

GE, gastroesophageal; RAO, right anterior oblique.

swallow emphasizes motion recording (video), utilizes a tightly controlled examination protocol (Table 41.7), and requires an understanding of esophageal physiology.

Videotaping the study greatly aids the evaluation, providing the surgeon with a real-time assessment of swallowing function, bolus transport, and the size and reducibility of an associated hiatal hernia. Given routine review before antireflux surgery, the value of the study becomes increasingly clear. The examination provides structural information including the presence of obstructing lesions and anatomic abnormalities of the foregut. A hiatal hernia is present in more than 80% of patients with GE reflux and is best demonstrated with the patient in the prone position, which causes increased abdominal pressure and promotes distention of the hernia above the diaphragm. The presence of a hiatal hernia is an important component of the underlying pathophysiology of GE reflux. Other relevant findings include a large (>5 cm) or irreducible hernia, suggesting the presence of a shortened esophagus; a tight crural “collar” that inhibits barium transit into the stomach, suggesting a possible cause of dysphagia; and the presence of a paraesophageal hernia.

Lower esophageal narrowing resulting from a ring, stricture, or obstructing lesion is optimally viewed with full distention of the esophagogastric region. A full-column technique with distention of the esophageal wall can be used to discern extrinsic compression of the esophagus. Mucosal relief or double-contrast films should be obtained to enhance the detection of small esophageal neoplasms, mild esophagitis, and esophageal varices. The pharynx and upper esophageal sphincter are evaluated in the upright position, and an assessment of the relative timing and coordination of pharyngeal transit is possible.

The assessment of peristalsis on video esophagram often adds to, or complements, the information obtained by esophageal motility studies. This is in part because the video barium study can be done both upright and supine and with liquid and solid bolus material, which is not true of a stationary motility examination. This is particularly true with subtle motility abnormalities. During normal swallowing, a stripping wave (primary peristalsis) is generated that completely clears

the bolus. Residual material can stimulate a secondary peristaltic wave, but usually a second pharyngeal swallow is required. Motility disorders with disorganized or simultaneous esophageal contractions have “tertiary waves” and provide a segmented appearance to the barium column, often referred to as beading or corkscrewing. In dysphagic patients, a barium-impregnated marshmallow, bread, or hamburger is a useful adjunct, which can discern a functional esophageal transport disturbance not evident on the liquid barium study. Reflux is not easily seen on video esophagram, and motility disorders that cause retrograde barium transport may be mistaken for reflux.

Assessment of the stomach and duodenum during the barium study is a necessity for proper preoperative evaluation of the patient with GERD. Evidence of gastric or duodenal ulcer, neoplasm, or poor gastroduodenal transit has obvious importance in the proper preoperative evaluation.

Assessment of Esophageal Function. The presence of poor esophageal body function can impact the likelihood of relief of regurgitation, dysphagia, and respiratory symptoms following surgery and may influence the decision to undertake a partial rather than a complete fundoplication. When peristalsis is absent or severely disordered, many surgeons would opt for a partial fundoplication, although recent studies would suggest a complete fundoplication may be appropriate even in this setting. The less favorable response of atypical, compared with typical, reflux symptoms after fundoplication may be related to persistent poor esophageal propulsive function and the continued regurgitation of esophageal contents.^{148,149}

The function of the esophageal body is assessed with esophageal manometry. Conventional water-perfused or solid-state manometry is performed with five pressure transducers located in the esophagus (Fig. 41.24). To standardize the procedure, the most proximal pressure transducer is located 1 cm below the well-defined cricopharyngeal sphincter. With this method, a pressure response along the entire esophagus can be obtained during one swallow. The study consists of recording 10 wet swallows with 5 mL of water. Amplitude, duration,

FIGURE 41.24. Illustration of the position of a five-channel esophageal motility catheter during the esophageal body portion of the study.

and morphology of contractions following each swallow are all calculated at the five discrete levels within the esophageal body (Fig. 41.25). The delay between onset or peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation and represents the degree of peristaltic activity.

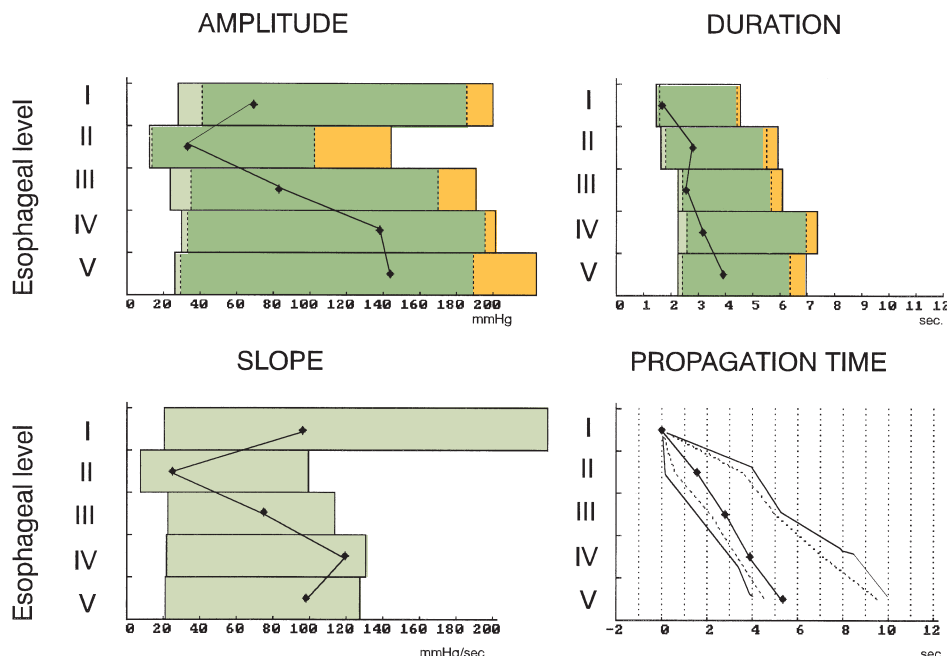

FIGURE 41.25. Computer-generated graphic representation of esophageal body contraction amplitudes, duration of contraction, and wave progression.

Recently, high-resolution manometry (ManoScan³⁶⁰, Sierra Scientific Instruments, Los Angeles, CA) has been introduced into clinical practice and may possess several advantages over the other manometric systems currently available.¹⁵⁰ The high-resolution catheter is 4.2 mm in diameter and has 36 solid-state transducers spaced at 1-cm intervals, compared to the standard 3- to 5-cm spacing of traditional water-perfused or solid-state catheters. Pressure transduction technology allows each of the sensors to detect pressure over a length of 2.5 mm in 12 radially dispersed sectors. The pressure of each sector is averaged, making each of the 36 sensors a circumferential pressure detector. This construct allows a more thorough and precise evaluation of esophageal function than standard manometry. In addition, given the number and span of transducers across the length of the catheter, the upper esophageal sphincter, esophageal body, and lower esophageal sphincter can be assessed simultaneously without moving the catheter. Thus, the study can be performed more quickly and with improved patient comfort compared to conventional manometry in that multiple repositionings of the catheter are not required to complete the evaluation. The experience in our laboratory has been that high-resolution manometry takes, on average, only 8.1 minutes to complete, whereas standard manometry with a solid-state catheter takes 24.4 minutes ($p < 0.0001$).¹⁵⁰ Finally, the color-coded readouts allow for a better, more intuitive, graphic description of the motor activity of the esophagus, the characteristics of the lower esophageal sphincter, and the presence of a hiatal hernia compared to the other technologies (Fig. 41.26). The catheter, however, is expensive with a high replacement cost should it break. With increasing experience and further study, the pros and cons of this new technology will continue to be elucidated.

Assessment of Gastric Function. Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Symptoms suggestive of gastroduodenal pathology include nausea, epigastric pain, anorexia, and early satiety. Abnormalities of gastric motility or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. If not identified before surgery, unrecognized gastric motility abnormalities are occasionally “unmasked” by an antireflux procedure, resulting in disabling postoperative symptoms.¹⁵¹ Considerable experience and judgment are necessary to identify the patient with occult gastroduodenal

FIGURE 41.26. High-resolution manometry (HRM) display. Note the color-coded graphic description of esophageal body wave amplitudes and lower esophageal sphincter function.

dysfunction. The surgeon should maintain a keen awareness of this possibility and investigate the stomach given any suggestion of problems. Tests of duodenogastric function that are helpful when investigating the patient with GE reflux include gastric emptying studies, gastric acid analysis, 24-hour gastric pH monitoring, and ambulatory bilirubin monitoring of the esophagus and stomach.

Poor gastric emptying or transit can provide for reflux of gastric contents into the distal esophagus. Standard gastric emptying studies are performed with radionuclide-labeled meals. They are often poorly standardized and difficult to interpret. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-minute intervals for 1.5 to 2 hours. After correction for decay, the counts in the gastric area are plotted as percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59% of a meal within 90 minutes.

Evolving Technologies for Assessment of Extraesophageal Manifestations of GERD. Given the difficulty inherent in proving that GERD is etiologic to extraesophageal symptoms, such as cough, sore throat, or hoarseness, or to more chronic and insidious conditions, such as repetitive aspiration or pulmonary fibrosis, a great interest exists to develop testing modalities that are both more sensitive and more specific than the technologies widely utilized at present. Several recent testing paradigms have emerged that appear promising, despite lacking extensive data.

Simultaneous 24-hour MII-pH and continuous pulse oximetry recently was evaluated in 20 subjects with primary respiratory symptoms (RSs) and 10 with primary esophageal symptoms (ESs).¹⁵² Oxygen saturation monitoring was performed using a finger clip probe (Pulsox-300i, Konica Minolta Sensing, Inc., Ramsey, NJ) that measures the arterial oxygen saturation (SpO₂) and pulse rate every second via standard photometrics (Fig. 41.27). An oxygen desaturation event was defined by either (a) SpO₂ less than 90% or (b) SpO₂ drop of 6% or greater (Fig. 41.28). Reflux events, both acid and nonacid, were temporally correlated to desaturation events. Markedly more reflux events were associated with desaturation in patients with RSs (74.5%, 832/1,117 reflux events) than in patients with ESs (30.4%, 223/734 reflux events, $p < 0.0001$) (Fig. 41.29). In addition, the difference in reflux desaturation association was more pronounced with proximal reflux (80.3% with RSs vs. 20.4% with ESs, $p < 0.0001$). While a number of issues still need to be resolved with this technique for it to be considered reliable and useful, the obser-

vation of oxygen desaturations in temporal proximity to reflux events, particularly in patients with RSs, is intriguing and may prove meaningful.

A pharyngeal pH catheter (ResTech, San Diego, CA) also was recently developed and consists of a thin (1.5-mm diameter) nasally passed catheter that can be positioned in the pharynx with the assistance of a light-emitting diode (LED) mounted on the tip. The catheter, being small, is well tolerated and measures both liquid and aerosolized reflux events. Optimal pH thresholds are currently being evaluated to predict the responsiveness of extraesophageal symptoms to antireflux therapy, either medical or surgical.

Finally, several centers have investigated the utility of salivary/sputum or laryngoscopic biopsy specimen assays for pepsin as a marker for underlying GERD.^{153–155} As pepsin is produced only in the gastric mucosa, its presence in the sputum or larynx reflects gastric reflux. Pepsin assays, when compared to ambulatory pH monitoring, showed a high correlation to proximal reflux events. Positive assays were also highly correlated with the presence of laryngopharyngeal reflux symptoms. Still lacking are data showing that a positive sputum or laryngeal pepsin assay predicts a successful symptomatic response to antireflux therapy. With additional study, the utility and reliability of each of these modalities will be determined in the clinical marketplace.

Partial Versus Complete Fundoplication. The decision between partial and complete fundoplication and an open or laparoscopic approach requires considerable judgment. Two randomized

FIGURE 41.27. Pulsox-300i with finger probe used to assess ambulatory oxygen saturation (Konica Minolta Sensing, Inc.).

FIGURE 41.28. Example of the association between a reflux episode detected by multichannel intraluminal impedance–pH study and oxygen desaturation detected by pulse oximetry. (Reproduced with permission from Salvador R, Watson TJ, Herbella F, et al. Association of gastroesophageal reflux and O₂ desaturation: a novel study of simultaneous 24-h MII-pH and continuous pulse oximetry. *J Gastrointest Surg* 2009; 13:854–861.)

studies of unselected patients undergoing laparoscopic fundoplication have shown equivalence of complete and partial fundoplications, anterior in one study¹⁵⁶ and posterior in the other,⁸³ in terms of operative time, perioperative morbidity, and hospital stay. Watson et al.¹⁵⁶ noted that resting and residual LES pressures were greater after complete fundoplication and that esophageal clearance of liquid radioisotope was prolonged in these patients compared with after partial fundoplication. Six months after operation, partial fundoplication was linked to a greater overall level of patient satisfaction manifested by a lower incidence of the symptoms of dysphagia, inability to belch, and excessive flatus. Laws et al.¹⁵⁷ did not identify any difference in symptomatic outcome between patients treated by complete and those treated by posterior partial fundoplication at a mean follow-up time of 27 months.

Hagedorn et al. reported on the results of a randomized, controlled trial comparing total (Nissen-Rosetti) and posterior

partial (Toupet) fundoplication in which long-term efficacy was assessed.¹⁵⁸ A total of 110 patients (54 undergoing a total wrap, 56 a partial wrap) completed a median follow-up of 11.5 years. No significant differences were observed between the groups in terms of heartburn, regurgitation, or dysphagia scores. A significant difference, however, was noted in the prevalence of rectal flatus and postprandial fullness, which were reported more often by those having undergone a total fundoplication.

A recent prospective, randomized trial from Australia comparing laparoscopic Nissen fundoplication to an anterior 180-degree partial fundoplication similarly revealed no significant differences between the two groups with regard to reflux symptoms, dysphagia, abdominal bloating, ability to belch, and overall satisfaction at 10 years' follow-up.¹⁵⁹

These observations, however, must be tempered by reports questioning the durability of partial fundoplications. Jobe et al. found that 51% of patients studied by 24-hour esophageal pH monitoring after Toupet fundoplication still had pathologic acid exposure.¹⁶⁰ Disturbingly, only 40% of the refluxers were symptomatic. Two studies have identified the presence of a defective LES function, an aperistaltic distal esophagus, and higher grades of esophagitis (Savary-Miller grades 2 to 4) as risk factors for partial fundoplication failure.^{158,160} Bell et al. reported recurrent reflux in 14% after Toupet fundoplication.¹⁶¹ The presence of mild esophagitis and a normal LES were associated with a 3-year success rate of 96%, whereas the presence of complicated esophagitis or a defective LES lowered this value to 50% (Fig. 41.23).

These findings highlight an apparent paradox, in that partial fundoplications afford suboptimal reflux protection in those most at risk from the effects of unabated GERD. The question arises, therefore, whether total fundoplication should be applied more liberally to patients with severe reflux disease and associated esophageal dysmotility. Patti et al. recently reported on 357 patients undergoing antireflux surgery, 235 undergoing a “tailored approach” with either a partial or total fundoplication depending on the results of preoperative manometry, and 122 more recent patients undergoing a total fundoplication regardless of the quality of esophageal peristalsis.¹⁶¹ In the first group, heartburn from pathologic reflux, confirmed by postoperative ambulatory esophageal pH monitoring, recurred in 19% after partial fundoplication and in 4% after total fundoplication. In the latter group, heartburn recurred in 4% after total fundoplication. Importantly, the incidence of postoperative dysphagia was similar in the two groups. This recent evidence, as well as our own experience, has led us to utilize the complete fundoplication more readily,

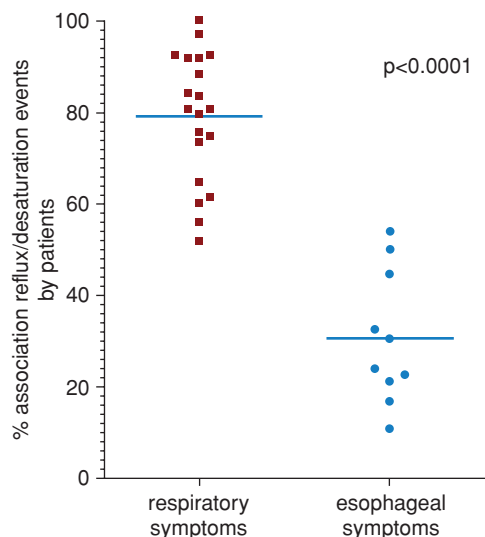

FIGURE 41.29. Scatterplot of association between reflux episodes and desaturation events by patient group. The prevalence of reflux-associated desaturations was remarkably different between the two groups ($p < 0.0001$). (Reproduced with permission from Salvador R, Watson TJ, Herbella F, et al. TABLE 41.8 MANAGEMENT**ELEMENTS OF LAPAROSCOPIC FUNDOPLICATION**

1. Crural dissection, identification and preservation of both vagi including the hepatic branch of the anterior vagus
2. Circumferential dissection of the esophagus
3. Crural closure
4. Fundic mobilization by division of short gastric vessels
5. Creation of a short, loose fundoplication by enveloping the anterior and posterior wall of the fundus around the lower esophagus

particularly in patients with Barrett esophagus. Currently, partial fundoplication is best reserved for patients with severe esophageal dysmotility approaching aperistalsis, such as occurs in scleroderma, or in combination with a distal esophageal myotomy for achalasia.¹⁶²

Laparoscopic Nissen Fundoplication. The performance of laparoscopic fundoplication should include the steps identified in Table 41.8.

Port Placement. Five ports are used (Fig. 41.30). The camera is placed above and to the left of the umbilicus, roughly one third of the distance to the xiphoid process. In most patients, placement of the camera in the umbilicus is too low to allow adequate visualization of the hiatal strictures once dissected. A transrectus location is preferable to midline to minimize the prevalence of port site hernia formation. Two lateral retracting ports are placed, one for the liver retractor in the right midabdomen (anterior axillary line), at or slightly below the camera port. This allows the proper angle toward the left lateral segment of the liver and thus the ability to push the retractor toward the operating table, lifting the liver. A second retraction port is placed slightly above the level of the umbilicus, in the

FIGURE 41.30. Trocar placement for laparoscopic antireflux surgery. The patient is placed with the head elevated 45 degrees in the modified lithotomy position. The surgeon stands between the patient's legs and the procedure is completed via five abdominal access ports.

left anterior axillary line. Placement of these ports too far lateral or too low on the abdomen will compromise the excursion of the instruments and thus the ability to retract. The left-sided operating port (surgeon's right hand) is placed 1 to 2 cm below the costal margin approximately at the lateral rectus border. Such placement allows triangulation between the camera and the two instruments and avoids the difficulty associated with the instruments being in direct line with the camera. The right-sided operating port (surgeon's left hand) is placed last, after the left lateral segment of the liver has been retracted. This placement prevents "sword fighting" between the liver retractor and the left-handed instrument. The falciform ligament hangs low in many patients and provides a barrier around which the left-handed instrument must be manipulated.

Hiatal Dissection. A fan or similar suitable retractor is placed into the right anterior axillary port and positioned to hold the left lateral segment of the liver toward the anterior abdominal wall. We prefer to use a table retractor to hold this instrument once properly positioned. Trauma to the liver should be meticulously avoided, because subsequent bleeding will obscure the field. Mobilization of the left lateral segment by division of the triangular ligament is not necessary. A Babcock or fundus clamp placed through the left anterior axillary port is used to grasp the GE fat pad and retract the stomach toward the patient's left foot. This maneuver exposes the esophageal hiatus. Commonly a hiatal hernia will need to be reduced. Atraumatic clamps should be used and care taken not to grasp the stomach too vigorously, as gastric perforations can occur.

Crural Dissection. Crural dissection begins with identification of the right crus. Metzenbaum-type scissors and fine grasping forceps are preferred for dissection. In all except the most obese patients, there is a very thin portion of the gastrohepatic omentum overlying the caudate lobe of the liver. The dissection is begun by incising the portion of the gastrohepatic omentum above and below the hepatic branch of the anterior vagal nerve (which some authors routinely spare). A large left hepatic artery arising from the left gastric artery is present in up to 25% of patients (Fig. 41.31); it should be identified and avoided. A right crural branch is occasionally seen, which can

FIGURE 41.31. Illustration of the initial dissection of the esophageal hiatus. The right crus is identified and dissected toward its posterior confluence with the left crus.

be divided. After incising the gastrohepatic omentum, the outside of the right crus will become evident. The peritoneum overlying the anterior aspect of the right crus is incised with scissors and electrocautery, and the right crus dissected from anterior to posterior as far as possible. The medial portion of the right crus leads into the mediastinum and is entered by blunt dissection with both instruments.

At this juncture the esophagus usually becomes evident. The right crus is retracted laterally with the surgeon's left-handed grasper and a modest dissection of the tissues posterior to the esophagus is performed. In most patients it is best not to dissect behind the GE junction at this time. Meticulous hemostasis is critical. Blood and fluid tend to pool in the hiatus and are difficult to remove. Irrigation should be avoided. Modest bleeding can be controlled by placing a 4×4 sponge into the abdomen. A large hiatal hernia often makes this portion of the procedure easier because it accentuates the diaphragmatic crura. On the other hand, dissection of a large mediastinal hernia sac can be difficult.

Following dissection of the right crus, attention is turned toward the anterior crural confluence. The tissues anterior to the esophagus are held upward by the left-handed grasper and the esophagus is swept downward and to the right, separating it from the left crus (Fig. 41.32). The anterior crural tissues are then divided and the left crus identified. The anterior vagus nerve often "hugs" the left crus and can be injured in this portion of the dissection if not carefully searched for and protected. The left crus is dissected as completely as possible, including taking down the angle of His and the attachments of the fundus to the left diaphragm (Fig. 41.33). A complete dissection of the lateral and inferior aspect of the left crus and fundus of the stomach is the key maneuver allowing circumferential mobilization of the esophagus. Failure to do so will result in difficulty encircling the esophagus, particularly if approached from the right. Repositioning of the Babcock retractor toward the fundic side of the stomach facilitates retraction for this portion of the procedure. The posterior vagus nerve may be encountered in the low left crural dissection and should be protected.

A window behind the GE junction can generally now be easily created. Attention is returned to the right side of the esophagus where the left-handed instrument is used to retract the esophagus anteriorly. This allows the right hand to perform the dissection behind the esophagus. The posterior vagus nerve should be identified and left on the esophagus. The left crus is identified and the dissection kept caudal to it. There is a tendency to dissect into the mediastinum and left pleura. In the presence of severe esophagitis, transmural inflammation,

FIGURE 41.32. Artistic depiction of division of the anterior crural fibers and mobilization of the esophagus off the left crus.

FIGURE 41.33. Left-sided crural dissection. The left crus is dissected as completely as possible and the attachments of the fundus of the stomach to the diaphragm are taken down.

esophageal shortening, or a large posterior fat pad, this dissection may be particularly difficult. If unduly difficult, abandon this route of dissection and approach the hiatus from the left side by dividing the short gastric vessels at this point in the procedure rather than later. After completing the posterior dissection, pass a grasper (through the surgeon's left-handed port) behind the esophagus and over the left crus and pull a Penrose drain around the esophagus to be used as an esophageal retractor for the remainder of the procedure.

Fundic Mobilization. Complete fundic mobilization allows construction of a tension-free fundoplication. This is best done by suspending the gastrosplenic omentum anteroposteriorly, in a clothesline fashion via two Babcock forceps, and opening into the lesser sac approximately one-third the distance down the greater curvature of the stomach (Fig. 41.34). The short

FIGURE 41.34. Illustration of the proper retraction of the gastrosplenic omentum facilitating the initial steps in short gastric division. Complete fundic mobilization is continued by retraction of the stomach rightward and the spleen and omentum left and downward. These maneuvers allow opening of the lesser sac and facilitate division of the high short gastric vessels.

FIGURE 41.35. The fundic mobilization is continued to include pancreaticogastric branches as well as the short gastric branches. Dissection continues until the crura and the caudate lobe can be seen from left posterior.

gastric vessels can then be sequentially dissected and divided with the aid of ultrasonic shears (Ethicon Endosurgery, Cincinnati, Ohio). An anterior-posterior rather than medial-to-lateral orientation of the vessels is preferred, with the exception of those close to the spleen. The dissection includes pancreaticogastric branches posterior to the upper stomach and continues until the right crus and caudate lobe can be seen from the left side (Fig. 41.35). With caution and meticulous dissection, the fundus can be completely mobilized in virtually all patients. Although generally possible via the right- and left-handed surgeon's access ports, occasionally this dissection requires removal of the liver retractor and placement of a second Babcock forceps through the right anterior axillary port to facilitate retraction during division of the short gastric vessels.

The relationship between complete fundic mobilization (short gastric vessel division) and postoperative dysphagia is a debate that has continued from the open era, when fundic mobilization was linked to a lower incidence of dysphagia. Two randomized studies have compared fundic mobilization with nonmobilization; one found no difference in outcome¹⁶³ and the other showed significant reductions in the incidence of dysphagia, gas bloat, and inability to belch after fundic mobilization.¹⁶⁴ The beneficial effect of fundic mobilization on these parameters has also been noted by other authors.¹⁶⁵ Whether fundic mobilization per se has a direct impact on dysphagia is unclear. It may simply be that mobilization permits better visualization of the procedure, thus ensuring that the repair is constructed with the posterior portion of the fundus.

Esophageal Mobilization and Crural Closure. The esophagus is mobilized into the posterior mediastinum for several centimeters to provide maximal intra-abdominal esophageal length. Posterior and right lateral mobilization is readily accomplished. In performing the anterior and left lateral mobilization, the surgeon must take care not to injure the anterior vagus nerve. Gentle traction on the Penrose drain around the GE junction facilitates exposure. The right and left pleural reflection often come into view and should be avoided. Con-

tinue the crural dissection to enlarge the space behind the GE junction as much as possible. Following mobilization and an assessment of intra-abdominal esophageal length, the hiatus is closed in all patients. The esophagus is held anterior and to the left and the crura approximated with two to four interrupted figure-of-eight 0-Ethibond sutures, starting just above the aortic decussation and working anterior. The authors prefer a large needle (CT1) passed down the left upper 10-mm port to facilitate a durable crural closure. Because space is limited, it is often necessary to use the surgeon's left-handed (nondominant) instrument as a retractor, facilitating placement of single bites through each crus with the surgeon's right hand. The aorta may be punctured while suturing the left crus. Identification of the anterior aortic surface and retracting the left crus via the left-handed grasper will help avoid inadvertent aortic puncture. The authors prefer extracorporeal knot tying using a standard knot pusher or a "tie knot" device (LSI Solutions, Victor, New York), although tying within the abdomen is perfectly appropriate. More recently, we have inspected the crural closure at the completion of the procedure following creation of the fundoplication and removal of the bougie. Doing so will often reveal that the bougie has dilated the hiatal opening such that a final stitch should be placed to further approximate it. Although there have been no randomized studies evaluating the role of routine crural closure, there is compelling evidence to indicate that closure should be standard. Watson et al.¹⁶⁶ identified paraesophageal herniation in 17 of 253 patients (7%), the frequency being 3% in those who had undergone crural repair and 11% in those who had not.

Creation of the Fundoplication. A short, loose fundoplication is fashioned with particular attention to the geometry of the wrap (Fig. 41.36). The midposterior fundus is grasped and passed left to right behind the esophagus rather than pulling right to left. This ensures that the posterior fundus is used for the posterior aspect of the fundoplication. This is accomplished by placing a Babcock clamp through the left lower port and grasping the midportion of the posterior fundus (Fig. 41.37). One should gently bring the posterior fundus behind the esophagus to the right side with an upward, rightward, and clockwise twisting motion. This maneuver can be difficult, particularly for the novice. If so, placement of a 0-silk suture in the midposterior fundus and grasping it from the right side facilitates bringing the posterior fundus around to create the

FIGURE 41.36. Schematic representations of the various possibilities of orientation of a Nissen fundoplication. The top set of figures represents the preferred approach, whereas the bottom two sets can be seen to result in twisting of the fundoplication.

FIGURE 41.37. Placement of Babcock on the posterior fundus in preparation for passing it behind the esophagus to create the posterior or right lip of the fundoplication. *Inset:* To achieve the proper angle for passage, the Babcock is placed through the left lower trocar. The posterior fundus is passed left to right and grasped from the right via a Babcock through the right upper trocar. **A:** Location of posterior fundus for passage to the right side. **B:** The posterior fundus passed underneath the esophagus and grasped on the right.

fundoplication. The anterior wall of the fundus is then folded over the esophagus to meet the posterior at about the 10 to 11 o'clock position above the supporting Penrose drain.

The posterior and anterior fundic lips should be maneuvered (as in a “shoe shine”) to allow the fundus to envelope the esophagus without twisting. Laparoscopic visualization has a tendency to exaggerate the size of the posterior opening that has been dissected. Consequently, the space for the passage of the fundus behind the esophagus may be tighter than thought and the fundus relatively ischemic when brought around. If the right lip of the fundoplication has a bluish discoloration, the stomach should be returned to its original position and the posterior dissection enlarged. A 60-French bougie is passed to properly size the fundoplication, and the “lips” of the fundoplication sutured utilizing a single U-stitch of 2-0 Prolene buttressed with felt pledgets. The most common error is an attempt to grasp the anterior portion of the stomach to construct the right lip of the fundoplication rather than the posterior fundus. The esophagus should comfortably lie in the untwisted fundus prior to suturing. Finally, two anchoring sutures of 2-0 silk or Ethibond are placed above and below the U-stitch to complete the fundoplication. When finished, the suture line of the fundoplication should be facing in a right anterior direction (Fig. 41.38). The abdomen is then irrigated, hemostasis checked, and the bougie, Penrose drain, and any sponges placed into the abdomen removed.

Transthoracic Nissen Fundoplication. The indications for performing an antireflux procedure by a transthoracic approach are given in Table 41.9.

In the thoracic approach the hiatus is exposed through a left posterior lateral thoracotomy incision in the sixth intercostal space (i.e., over the upper border of the seventh rib). When necessary, the diaphragm is incised circumferentially 2 to 3 cm from the lateral chest wall for a distance of approximately 10 to 15 cm. The esophagus is mobilized from the level of the diaphragm to underneath the aortic arch. Mobilization up to the aortic arch is usually necessary to place the repair in a patient with a shortened esophagus into the abdomen without undue tension. Failure to do this is one of the major causes for subsequent breakdown of a repair and return of symptoms. The cardia is then freed from the diaphragm. When all the attachments between the cardia and diaphragmatic hiatus

are divided, the fundus and part of the body of the stomach are drawn up through the hiatus into the chest. The vascular fat pad that lies at the GE junction is excised. Crural sutures are then placed to close the hiatus though are not tightened until later. The fundoplication is constructed by enveloping the fundus around the distal esophagus in a manner similar to that described for the abdominal approach. When complete, the fundoplication is placed into the abdomen by compressing the fundic ball with the hand and manually maneuvering it through the hiatus. The previously placed crural stitches are then tightened and knotted.

Collis Gastroplasty. In patients with a short esophagus secondary to a stricture, Barrett esophagus, or a large hiatal hernia,

FIGURE 41.38. Fixation of the fundoplication. The fundoplication is sutured in place with a single U-stitch of 2-0 Prolene pledgeted on the outside. A 60-French mercury-weighted bougie is passed through the gastroesophageal junction prior to fixation of the wrap to ensure a floppy fundoplication. Inset illustrates the proper orientation of the fundic wrap.

TABLE 41.9

INDICATIONS/CONTRAINDICATIONS

INDICATIONS FOR PERFORMING AN ANTIREFLUX PROCEDURE BY A TRANSTHORACIC APPROACH

■ INDICATION	■ EXPLANATION
Previous hiatal hernia repair	In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
Concomitant procedure	Concomitant esophageal myotomy for achalasia or diffuse spasm.
Short esophagus	This is usually associated with a stricture or Barrett esophagus. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus, the performance of a Collis gastroplasty, or, if necessary, placement of the repair without tension below the diaphragm.
Sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position	This can indicate esophageal shortening and, again, a thoracic approach is preferred for maximum mobilization of the esophagus and, if necessary, the performance of a Collis gastroplasty.
Associated pulmonary pathology	The nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.
Obesity	The abdominal repair is difficult because of poor exposure, whereas the thoracic approach gives better exposure and allows a more precise repair.

the esophagus is lengthened with a Collis gastroplasty. The gastroplasty lengthens the esophagus by forming a gastric tube or “neoesophagus” along the lesser curvature. The procedure allows a tension-free construction of a total or partial fundoplication around the newly formed gastric tube, with placement of the repair in the abdomen. A gastroplasty can be readily performed via either an abdominal or thoracic approach. A number of techniques have been reported for the laparoscopic performance of Collis gastroplasty, and the surgeon opting to manage the shortened esophagus laparoscopically must be able to perform such a procedure should the need arise.¹⁶⁷

Outcomes Following Antireflux Surgery. Any discussion regarding results following fundoplication must consider:

1. Perioperative morbidity and mortality
2. Control of typical and atypical symptoms
3. Side effects
4. Objective relief from excessive esophageal acid exposure
5. Anatomic failure rates, such as recurrent hiatal herniation or slippage, and the need for reoperation

Complications of Antireflux Surgery. Carlson and Frantzides¹⁶⁸ reported on complications and results of primary minimally invasive antireflux operations based on a literature review. Included in their analysis were 41 papers comprising 10,489 procedures. Postoperative complications were found to occur in approximately 8% of patients, with the rate of conversion to an open procedure of about 4%. The most common perioperative complication was early wrap herniation (1.3%), defined as occurring within 48 hours of surgery. This is one complication that may be more common with the laparoscopic than open approach. The explanation for this is unclear but may be related to the opening of tissue planes by the pneumoperitoneum and the reduced tendency for adhesion formation after laparoscopic compared to open surgery. In an attempt to eliminate this complication, most surgeons routinely perform a crural repair.

Both pneumothorax and pneumomediastinum have been reported. The occurrence of pneumothorax is related to breach of either pleural membrane, usually the left, during the hiatal dissection. Chest drain insertion is usually not required because accumulated carbon dioxide rapidly dissipates following release of pneumoperitoneum by a combination of positive-pressure ventilation and absorption.

As with any laparoscopic procedure, instrumental perforation of the hollow viscera may occur. Early esophageal perforation may arise during passage of the bougie, during the retroesophageal dissection, or during suture pull-through. Late esophageal perforation is related to diathermy injury at the time of mobilization. Gastric perforations usually result from excessive traction on the fundus for retraction purposes. Recognition of the problem at the time of surgery requires repair, which may be performed either laparoscopically or by an open technique.

Hemorrhage during the course of laparoscopic fundoplication usually arises from the short gastric vessels or spleen. Rarer causes include retractor trauma to the liver, injury to the left inferior phrenic vein, an aberrant left hepatic vein, or the inferior vena cava. Cardiac tamponade as a result of right ventricular trauma has also been reported. Major vascular injury mandates immediate conversion to an open procedure to achieve hemostasis. One complication that has been virtually eliminated since the advent of laparoscopic fundoplication is incidental splenic injury necessitating splenectomy (0.06%), which occurred with a frequency of around 2% to 5% during the open era. The mortality rate for primary minimally invasive antireflux surgery has fortunately been quite low, reported at 0.08%.

Symptomatic Outcomes Following Antireflux Surgery. Studies of long-term outcome following both open and laparoscopic fundoplication document the ability of laparoscopic fundoplication to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80% to 90% of patients 5 years or more following surgery.^{169–177} The data include evidence-based reviews of antireflux surgery,¹⁷⁴ prospective randomized trials comparing antireflux surgery to PPI therapy¹⁷⁵ and open to laparoscopic fundoplication,¹⁷⁶ and analysis of U.S. national trends in utilization and outcomes.¹⁷⁷ The results of laparoscopic fundoplication compare favorably with those of the “modern” era of open fundoplication. They also indicate the less predictable outcome of atypical reflux symptoms (cough, asthma, laryngitis) after surgery being relieved in only two thirds of patients.¹⁷⁸

A few recent trials deserve emphasis. Results were updated on a prospective, randomized trial comparing PPI therapy to antireflux surgery.¹⁷⁹ The outcome of the study previously had been reported at a follow-up of 5 years,¹⁷⁵ while the latest

update provided follow-up of at least 7 years. The proportion of patients in whom treatment did not fail during the 7 years was significantly higher in the surgical arm than in the medical arm. A smaller difference in outcomes was noted after dose adjustments in the medical group. More patients in the surgical cohort, however, complained of side effects such as dysphagia, inability to belch or vomit, and hyperflatulence. Disease control was essentially stable between 5 and 7 years of follow-up. The authors concluded that surgery was more effective in controlling overall GERD symptoms, though post-fundoplication side effects were a concern.

Another prospective trial from the United Kingdom compared laparoscopic Nissen fundoplication to PPI and reported follow-up at a median of 6.9 years.¹⁸⁰ Some patients initially randomized to PPI therapy were offered the opportunity to undergo surgery. While both the medical and surgical cohorts reported an improvement in GERD-related symptoms after 12 months, further symptomatic improvement was noted in those patients subsequently undergoing surgery despite optimal PPI therapy.

A multicenter, European, prospective randomized trial comparing laparoscopic antireflux surgery (LARS) to medical therapy with esomeprazole is ongoing (the LOTUS trial). Three-year outcomes in 288 patients assigned to LARS and 266 assigned to medical therapy were reported in 2008.¹⁸¹ The proportion of patients remaining in symptomatic remission was similar between the two groups (90% for LARS, 93% for medical therapy in an intention-to-treat analysis, $p = 0.25$). No major perioperative complications were noted and esomeprazole appeared to be well tolerated.

Recent reports have called attention to the observation that many patients are prescribed acid suppression medications after antireflux surgery. Spechler et al. reported on the long-term follow-up of patients with complicated GERD enrolled in the Department of Veterans Affairs randomized trial of medical versus surgical therapies.^{182,183} In the first report, almost half (46.9%) of the patients treated by fundoplication had taken acid suppression medications at some point during the 11- to 13-year follow-up period.¹⁸² In the second report, 62% of the surgically treated patients had used medications.¹⁸³

Lord et al.¹⁸⁴ reported on 86 patients who had symptoms after Nissen fundoplication severe enough to warrant evaluation with 24-hour ambulatory esophageal pH monitoring. Thirty-seven (43%) of these patients were taking acid suppression medications, and only 9 of them (24%) were found to have abnormal pH scores. Heartburn and regurgitation were the only symptoms that were significantly associated with an abnormal pH study. Multivariable logistic regression analysis showed that patients with a disrupted, abnormally positioned fundoplication had a 52.6 times increased risk of abnormal esophageal acid exposure. Based on these data, most patients using acid suppression medications after antireflux surgery do not have abnormal esophageal acid exposure. Objective evidence of reflux should be obtained in patients who complain of postoperative symptoms.

The goal of surgical treatment for GERD is to relieve the symptoms of reflux by re-establishing the GE barrier. The challenge is to accomplish this without inducing dysphagia or other untoward side effects. Dysphagia that existed prior to surgery usually improves following laparoscopic fundoplication. Temporary dysphagia is common after surgery and generally resolves within 3 months. Dysphagia persisting beyond 3 months has been reported in up to 10% of patients. In our experience, dysphagia, manifested by occasional difficulty in swallowing solids, was present in 7% of patients at 3 months, 5% at 6 months, 2% at 12 months, and a single patient at 24 months following surgery.¹⁷⁰ Others have observed a similar improvement in postoperative dysphagia with time. Induced dysphagia is usually mild, does not require dilatation, and is temporary. It can be induced by technical misjudgments, but this explanation does not hold in all instances. In experienced hands, its prevalence should be less than 3% at 1 year. Other

side effects common to antireflux surgery include the inability to vomit and increased flatulence. Most patients cannot vomit through an intact wrap, though this is rarely clinically relevant. Hyperflatulence is a common and noticeable problem, likely related to increased air swallowing that is present in most patients with reflux disease.

Objective Outcomes Following Antireflux Surgery. Laparoscopic fundoplication results in a significant increase in LES pressure and length, generally restoring these values to normal. The ability of an antireflux operation to restore esophageal acid exposure to normal depends on the type of fundoplication performed. Complete (Nissen) fundoplications generally are more reliable and durable than partial (e.g., Toupet) fundoplications at preventing pathologic acid reflux. Objective studies have shown that more than 90% of patients will have normal pH studies at 1 to 3 years following complete fundoplication, whereas only 50% of patients will have normal esophageal acid exposure following a partial fundic wrap.¹⁶⁰

Quality-of-life analyses have become an important part of surgical outcome assessment, with both generic and disease-specific questionnaires in use, in an attempt to quantitate quality of life before and after surgical intervention. In general, these measures relate the effect of disease management to the overall well-being of the patient.¹⁸⁵ Most studies have utilized the Short Form 36 (SF-36) instrument, because it is rapidly administered and well validated. This questionnaire measures 12 different health-related quality-of-life parameters encompassing mental and physical well-being. Data from Los Angeles indicate significant improvements in scores for the area of bodily pain and in a portion of the general health index.¹⁷⁰ Most other measures were improved but failed to achieve statistical significance. Trus et al.¹⁸⁶ have also analyzed SF-36 scores before and after laparoscopic antireflux surgery. In contrast to our data, scores in all fields were significantly better after surgery. In this study, preoperative scores were dramatically lower than were found in our study. Thus, the difference is likely to be secondary to the relatively high scores of our patients prior to surgery (perhaps reflecting good disease control on medical therapy) and to our small sample size.

Other investigators have also reported improvement in quality of life following antireflux surgery. Glise et al.¹⁸⁷ utilized two standardized and validated questionnaires, the Psychological General Well-Being Index and the Gastrointestinal Symptom Rating Scale, to evaluate quality of life in a cohort of 40 patients following laparoscopic antireflux surgery. Scores with both instruments were improved following antireflux surgery and better than in untreated patients. Of particular note was that scores were as good as or better than those of patients receiving optimal medical therapy. Velonovich et al.,¹⁸⁸ using a 10-item health-related quality-of-life questionnaire specific for GERD, have also shown an improvement in quality of life following antireflux surgery.

Fernando et al.¹⁸⁹ reported on quality of life after antireflux surgery compared with nonoperative management for severe GERD. Follow-up quality of life was measured using the SF-36, and heartburn severity was measured using the Health-Related Quality of Life (QOL) scale. Detailed outcomes were available for 101 surgical patients and 37 medical patients. Mean QOL scores were better in the surgical group. More of the medical patients were dissatisfied with therapy. SF-36 scores were better in six of eight domains for surgical patients. These data support the notion that antireflux surgery, performed on properly selected patients, can significantly improve quality of life and may outperform medical therapy in this regard.

Anatomic Failure Following Antireflux Surgery. An important and often underemphasized point is that the rate of failure of fundoplication is largely dependent upon the size of the underlying hiatal hernia. Repair of large sliding and paraesophageal hernias (PEHs) is associated with a higher risk of recurrent

hiatal herniation compared to fundoplication for GERD in the setting of no or small hiatal hernias. Multiple potential explanations exist to explain this differential, including the presence of a widened hiatus with weakened or attenuated crural fibers that must be brought together under tension, the coexistence of esophageal body shortening, the generally older and frailer nature of patients with a PEH, and underlying anatomic, muscular, or connective tissue deficits that contributed to the pathogenesis of the hernia. In particular, the association between kyphosis and intrathoracic stomach is becoming increasingly recognized, as skeletal abnormalities likely are contributory to the pathogenesis of paraesophageal hiatal herniation.¹⁹⁰

The need for reoperation after fundoplication for GERD is only approximately 5% over the patient's lifetime, whereas the risk can run as high as 42% after repair of a giant PEH.¹⁹¹ In a trial from Finland, objective outcomes were assessed by endoscopy and demonstrated a 40% disruption rate following open Nissen fundoplication and a 13% disruption rate following a laparoscopic procedure.¹⁹² Despite these relatively high rates of objective breakdown, only 8% of patients in the open group and 2% in the laparoscopic group had undergone repeat operation for fundoplication failure.

A recent trial compared two techniques of laparoscopic PEH repair, with or without the use of a biologic prosthesis placed at the esophageal hiatus.¹⁹³ At 6 months, 9% of patients with the prosthesis and 24% of patients without mesh reinforcement had developed a recurrent hiatal hernia as assessed by a barium upper gastrointestinal examination, underscoring the potential for failure when operation is undertaken for PEHs.

Some surgeons routinely add a Collis gastroplasty as an esophageal lengthening procedure in the setting of fundoplication for giant PEHs given the high incidence of acquired esophageal body shortening associated with this condition.¹⁹⁴ Methods to reduce the risk of recurrent hiatal herniation following repair of giant PEHs, such as gastroplasty, mesh reinforcement, extensive esophageal mobilization, or use of open surgical approaches rather than laparoscopy, are areas of active ongoing investigation.

FUTURE DIRECTIONS

Medical therapy for GERD and antireflux surgery both have inherent drawbacks. Major limitations of acid suppressive medications include the inability to prevent regurgitation of weakly acidic or nonacidic refluxate and the need for chronic, continual therapy, not to mention the cost, inconvenience, potential side effects, and need for ongoing dietary and lifestyle modifications. In addition, current therapy does not address the main pathophysiologic contributor to the presence of GERD, the mechanically defective LES. Funduplications, while intended to permanently restore the LES, suffer from the potential for perioperative complications, a high initial cost, the risks inherent in general anesthesia, possible short- and long-term side effects, and inconsistent reflux control across centers. In addition, proper patient selection is critical and the operative technique is not well standardized, perhaps adversely affecting outcomes, particularly in inexperienced hands.

For all of these reasons, an interest remains to create means of restoring LES competence by medical or less invasive surgical or endoscopic techniques that are easily applied and highly reproducible. Medications such as baclofen, a γ -aminobutyric acid_B receptor agonist, have been utilized to decrease TLESRs, thereby decreasing GERD.¹⁹⁵ Similar investigational drugs are in the pipeline and likely will reach clinical practice soon. A number of endoluminal therapies have been devised and tested to date, including endoscopically injected agents for bulking of the LES, endoluminal suturing or valvuloplasty, and radiofrequency energy application to the LES, though most have been withdrawn from the marketplace.¹⁹⁶

Despite these notable recent failures, new devices continue to emerge and offer potential improvements over prior technologies. A transoral endoscopic fundoplication device (EsoPhyX, EndoGastric Solutions, Inc., Redmond, Washington) has been trialed in animal models and a limited number of human GERD patients.¹⁹⁷ Another device that creates an endoscopic, anterior partial fundoplication (Medigus SRS, Medigus, Ltd., Omer, Israel) has been tested in Europe, Australia, and India and is in early U.S. trials as of this time. Finally, magnetic augmentation of the LES via a laparoscopically placed ring of small magnets (TORAX Medical, Inc., Shoreview, Minnesota) is in clinical trials and offers the potential for a quick, highly reproducible, and effective means of chronic GERD control with low risk.¹⁹⁸ The long-term safety profile, as well as the symptomatic and objective success rates, of each of these devices awaits further study.

CHAPTER 42 ■ ESOPHAGUS: TUMORS AND INJURY

PHILIP A. RASCOE, JOHN C. KUCHARCZUK, AND LARRY R. KAISER

KEY POINTS

- 1 The high fat content of the esophageal submucosa leads to mobility of the overlying mucosa; therefore, care must be taken that every anastomotic suture transfixes the submucosa to prevent anastomotic leak.
- 2 The incidence of esophageal perforation has increased over recent decades due to the increasing use of invasive endoscopic procedures, such that iatrogenic injury by instrumentation accounts for more than 50% of all cases.
- 3 The management of esophageal perforation is dictated by the location and extent of the perforation, the clinical condition of the patient, and the presence or absence of underlying esophageal pathology.
- 4 Perforations of the upper third of the esophagus down to the level of the carina are treated by cervical drainage, most commonly via a left neck incision.
- 5 The management of an esophageal perforation associated with endoscopic dilatation for achalasia includes primary repair of the injury, a vertical esophageal myotomy performed 180 degrees opposite the injury, and a noncircumferential wrap such as a Belsey fundoplication.
- 6 The incidence of esophageal adenocarcinoma in the United States has increased in the last 25 years greater than the incidence of any other major malignancy.
- 7 The goal of surgical resection for esophageal cancer is cure, as effective palliation can be obtained with chemotherapy, radiation therapy, and endoscopic interventions such as stenting and laser fulguration.
- 8 Data concerning improved survival following neoadjuvant chemotherapy and radiation for esophageal cancer are inconclusive and must be considered in light of the associated toxicity of multimodality therapy.
- 9 Advantages of transhiatal esophagectomy are less surgical trauma by avoidance of a thoracotomy and placement of the anastomosis in the neck, which minimizes the morbidity of an anastomotic leak.
- 10 The intent of palliation of unresectable esophageal cancer is to maintain comfort, restore swallowing function if possible, and support nutrition.

The role of the esophagus is to propel food and secretions from the pharynx to the stomach. As such, it is primarily an organ of motility with no absorptive capacity. It also provides an important barrier function, isolating the mediastinum from the bacteria present in the mouth and external environment.

The esophageal anatomy is discussed in the previous chapter. Nevertheless, several specific anatomic points need to be highlighted when discussing surgery for injuries and tumors of the esophagus. First, indentations made on the esophagus by external mediastinal structures are clinically important. These indentations can be seen readily on esophagram (Fig. 42.1). The cricopharyngeus causes the first constriction of the esophagus and is a common location for iatrogenic perforations caused by instrumentation. The second indentation seen to the left of the esophagus is the aortic arch, which is a common location for food or foreign body impaction. The third indentation is the left mainstem bronchus.

In the adult, esophageal length is variable depending on upper body length. Nevertheless, the overall average length from the upper esophageal sphincter to the lower one approximates 24 cm or 10 inches. Because endoscopy plays an important role in the localization of esophageal injuries and tumors, esophageal locations are usually referenced relative to the distance from the incisors. Thus, on average, the esophagus begins at 16 cm from the incisors and ends at 38 to 40 cm from the incisors.

Externally, the esophagus is composed of an outer layer of longitudinal muscle and an inner layer of circular muscle. There is no serosal layer as ensheathes all other parts of the gastrointestinal tract. Transmural invasion by esophageal carcinoma is common because the tumor is not limited by overlying serosa or

pleura. This is in contrast to other gastrointestinal cancers, which usually extend to, but not through, the peritoneum.

- 1 Another important anatomic feature of the esophagus is the unique submucosal layer. This layer has a high fat content, which accounts for the mobility of the overlying mucosa. Because of this arrangement, care must be taken to ensure that every anastomotic suture transfixes the submucosa; if it does not “an anastomotic leak will occur when the mucosa retracts proximally and an accurate apposition of the mucosa is not achieved.”¹

The esophageal blood supply is segmental. The esophagus is vascularized by numerous arteries coursing through the lateral attachments, and it has an extensive submucosal collateral circulation. The cervical esophagus receives blood from the superior and inferior thyroid arteries. Multiple aortic esophageal arteries supply the intrathoracic esophagus and through collaterals connect with the inferior thyroid, intercostal, bronchial, inferior phrenic, and left gastric arteries. Improper control of these vessels during a transhiatal esophagectomy can result in significant blood loss.

The intramural lymphatic network of the esophagus is predominantly located within the submucosa. However, there are lymphatic channels within the lamina propria of the mucosa. This explains the occasional presence of nodal metastasis arising from superficial cancers.

The esophagus is innervated by the autonomic nervous system. The cervical esophagus receives parasympathetic innervation through the recurrent laryngeal branches of the vagus nerve. Thus, injury to the recurrent laryngeal nerve not only produces hoarseness and a poor cough but may also result in upper esophageal sphincter dysfunction predisposing to life-threatening aspiration following esophagectomy.

FIGURE 42.1. Barium contrast esophagography showing the constriction caused by the cricopharyngeal muscle, aortic arch, and the left mainstem bronchus. Indentations of the esophagus made by external structures are important anatomic landmarks and are often the sites of perforation due to instrumentation.

SURGICAL APPROACHES TO THE ESOPHAGUS

Multiple factors influence the surgical approach to the esophagus. These include the nature of the injury or neoplasm (benign vs. malignant), the overall health of the patient, and the expertise of the surgeon.

A complete working knowledge of the anatomic relationships between the esophagus and adjacent structures is vital to planning surgical therapy. The upper thoracic esophagus is in contact with the posterior membranous trachea, the left mainstem bronchus, and the aortic arch. Patients with cancers involving the upper thoracic esophagus must undergo preoperative bronchoscopy to rule out invasion of the posterior membranous trachea, because this precludes resection. Although flexible bronchoscopy may demonstrate gross airway invasion, rigid bronchoscopy is much more sensitive in determining adherence to the membranous trachea. Loss of the normal ripple effect as the rigid scope slides over the membranous trachea suggests the tumor is fixed to the airway and is not resectable. This is equally important where the esophagus passes under the left mainstem bronchus.

From a surgical perspective, the esophagus is divided into thirds. The upper third can be reached through a cervical incision. The middle third is best approached through the right chest, as access to the middle third of the esophagus from the left chest is obscured by the aorta. The distal third of the esophagus is best approached through the left chest. The short segment of intra-abdominal esophagus may be approached through the upper abdomen.

When esophagectomy is required, several surgical approaches have been described. These include the transhiatal approach,² the transabdominal transthoracic approach (Ivor Lewis),³ the three-stage or “three-hole” approach (McKeown),⁴ the thoracoabdominal approach, and the minimally invasive approach. Each approach has its own set of risks and benefits as well as outspoken opponents and proponents. Selection of the

appropriate approach requires experienced surgical judgment. Despite the rhetoric, several studies have shown equivalent outcomes among the multiple approaches. It appears that the experience of the surgeon⁵ and the number of cases performed at a particular institution are the leading factors determining outcome.⁶ Clearly, failures in technique that occur during the performance of an esophagectomy are associated with increased length of hospital stay and increased in-hospital mortality and are predictive of a poorer overall long-term survival.⁷

ESOPHAGEAL INJURY

Perforation

Despite decades of clinical experience and surgical innovation, perforation of the esophagus continues to present diagnostic and therapeutic challenges. Accurate diagnosis and early treatment are essential to the successful management of patients with esophageal perforation. Outcome is determined by the cause and location of the injury, the presence of concomitant esophageal disease, and the interval between perforation and initiation of therapy.

The causes of esophageal perforation are listed in Table 42.1. Over the past decade, the incidence of esophageal perforation has increased, and the most common etiology has become iatrogenic, due to the increasing use of invasive diagnostic and therapeutic endoscopic procedures. In our review of the literature, we found that iatrogenic injury to the esophagus by instrumentation accounted for 59% of all cases and spontaneous perforations accounted for only 15%.⁸

Other, less common injuries include foreign body ingestion (12%) and trauma (9%). Ingestion of foreign bodies or caustic materials can produce perforation most commonly in areas of anatomic narrowing including the cricopharynx, the segment where the aortic arch and left mainstem bronchus impinge on the esophagus, and at the distal esophageal sphincter. External penetrating trauma causes perforations mainly in the cervical esophagus, the portion not protected by the

TABLE 42.1

ETIOLOGY

CAUSES OF ESOPHAGEAL PERFORATION

INSTRUMENTAL

- Endoscopy
- Dilation
- Intubation
- Sclerotherapy
- Laser therapy

NONINSTRUMENTAL

- Barogenic trauma
 - Postemetic (Boerhaave syndrome)
 - Blunt chest or abdominal trauma
 - Other (e.g., labor, convulsions, defecation)
- Penetrating neck, chest, or abdominal trauma
- Operative trauma
 - Esophageal reconstruction (anastomotic disruption)
 - Vagotomy, pulmonary resection, hiatal hernia repair, esophagomyotomy
- Corrosive injuries (acid or alkali ingestion)
- Erosion by adjacent infection
- Swallowed foreign body

thoracic cage. The morbidity and mortality of penetrating esophageal trauma is usually the result of the associated injuries including major vascular and airway injuries.⁹ Blunt traumatic perforation is exceedingly rare but may be evident following motor vehicle accident or performance of the Heimlich maneuver.

Spontaneous, or barogenic, esophageal perforation results from a sudden increase in intraesophageal pressure. This has been associated with hyperemesis, childbirth, seizure, prolonged coughing, or weightlifting. Of special historical note are patients with Boerhaave syndrome. These patients develop perforation of the distal esophagus after the excessive ingestion of food and alcohol followed by violent emesis resulting in disruption of the distal esophagus with soilage into the left pleural cavity. This syndrome is named after Herman Boerhaave who, in 1723, provided a detailed account with post-mortem correlation of the esophageal perforation of the High Admiral of the Dutch Navy, Baron Van Wassenae.¹⁰ The admiral had attempted to relieve his postprandial discomfort by self-induced vomiting after having feasted richly on roast duck and beer.

Clinical Features

The presenting clinical features of esophageal perforation depend on the location of the perforation and the time interval between injury and presentation. Patients with cervical perforations generally present with cervical dysphagia, neck pain, dysphonia, and subcutaneous cervical emphysema. This is in distinction to patients with intrathoracic perforations, who often present with signs and symptoms of mediastinitis. These include tachycardia, tachypnea, fever, and leukocytosis. Perforations of the intra-abdominal esophagus result in soilage of the peritoneal cavity and present as an acute abdomen. As with thoracic perforations, patients present with tachycardia, tachypnea, fever, and leukocytosis. Systemic sepsis, rapid deterioration, and shock are common.

Diagnosis

The diagnosis of esophageal perforation begins with a high level of suspicion. Esophageal perforation must be ruled out in any patient presenting with cervical, thoracic, or abdominal pain following endoscopy. Contrast esophagography remains the gold standard for diagnosis, as it both confirms the diagnosis and localizes the site of perforation. Water-soluble contrast (e.g., Gastrografin) is the initial agent used for contrast esophagography. These agents demonstrate extravasation in 50% of cervical perforations and 80% of perforations located within the chest.¹¹ If no extravasation is seen with Gastrografin, thin barium should be used because it will demonstrate 60% of cervical perforations and 90% of intrathoracic perforations.¹² In patients with known or suspected aspiration risk, or in cases of suspected airway-esophageal fistula, barium contrast should be used alone because the hyperosmolar water-soluble contrast agents may cause rapid pulmonary edema and ventilatory collapse.

Flexible esophagoscopy may be used to directly visualize and localize the area of perforation. It has a sensitivity of 100% and a specificity of 80%.¹³ Proponents of flexible esophagoscopy use this technique for confirmation of the injury and in planning the surgical approach. Opponents of this practice argue that air insufflation enlarges the injury and results in further bacterial contamination. One particular case that warrants special discussion is a mucosal or submucosal tear without perforation. Clearly, endoscopy is contraindicated in these patients as air insufflation may convert this to a full-thickness injury, thus converting a problem that could be managed conservatively to one that requires surgical intervention. We routinely perform

flexible endoscopy in the operating room for localization in patients requiring operative management of their perforation. In the small subset of patients who will be treated conservatively, we avoid the practice.

Computed tomography (CT) scan is useful in localizing collections in the pleural space or mediastinum; it is not used to localize the primary site of perforation. We do not generally obtain this study on presentation, although many patients have this study performed prior to surgical consultation. Commonly, the recognition of pneumomediastinum on a CT scan obtained in the emergency department prompts surgical consultation. However, the real value of CT scanning is in the patient who remains septic following drainage and repair. The CT scan may reveal a collection requiring percutaneous or operative drainage.

Management

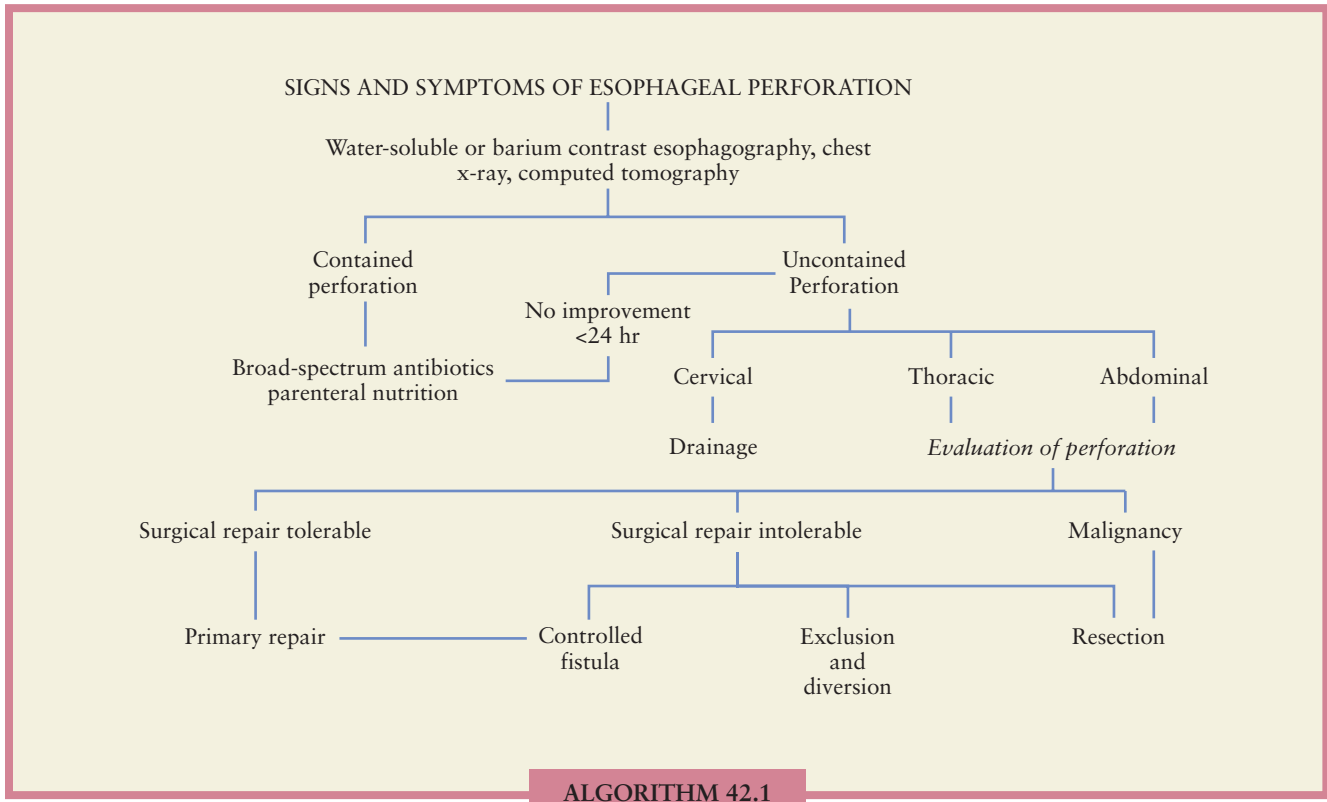

- 3 The treatment of esophageal perforation is dictated by the location of the perforation, the amount of soilage present, the clinical condition of the patient, and the presence of underlying esophageal pathology. While delay in presentation is associated with increased mortality, it is not a contraindication to definitive surgical repair. The goal of treatment is to stabilize the patient, stop ongoing soilage, control infection, and reestablish esophageal continuity. Our current protocol for management of esophageal perforations is outlined in Algorithm 42.1.

Nonoperative Treatment. In practice, only a very small subset of patients with esophageal perforation are appropriate for nonoperative treatment. The successful use of nonoperative therapy requires careful patient selection, sound surgical judgment, and repeated clinical evaluation. Because the stakes are so high, it must be recognized that operative treatment really is the more conservative approach. Selecting the wrong patient or making a poor judgment will lead to local complications, continued sepsis, and a potentially devastating outcome.

The first reported series of nonoperative treatment of esophageal perforation appeared in 1965 and included 18 patients with instrument perforations of the thoracic esophagus; there was only one death.¹⁴ In 1979, Cameron et al.¹⁵ established a set of criteria to aid in the selection of patients for nonoperative management. Currently, nonoperative management is appropriate for the treatment of all intramural dissections without evidence of frank full-thickness perforation. For transmural perforations, however, the approach can be considered only if (a) the perforation is well contained, (b) there is no associated esophageal malignancy, (c) the perforation is not in the abdominal cavity, (d) there is no simultaneous obstructive esophageal disease, and (e) there are no signs or symptoms of systemic sepsis.¹⁶

Nonoperative management begins with the administration of broad-spectrum antibiotics, the suspension of oral intake, and the institution of alternative nutrition either parenterally or enterally via a gastric or jejunal feeding tube. Vigilant monitoring for fever, tachycardia, and leukocytosis is necessary, as these findings are indicative of impending sepsis. Any clinical deterioration suggests failure of this approach and should prompt expedient operative intervention. From a practical standpoint, it is best to think in terms of operative management whenever esophageal perforation is suspected.

Stent Placement. Endoscopic placement of an endoluminal stent to palliate inoperable esophageal malignancy was first described in the 1970s.¹⁷ The past three decades have seen expanded indications and improved technology for esophageal stenting. There are an increasing number of small case series in the literature detailing stent placement for esophageal perforations. Attempts to stent the cervical esophagus cause dysphagia and aspiration, whereas stenting the distal esophagus and

esophagogastric junction is plagued by gastroesophageal reflux and stent migration. It appears that iatrogenic midthoracic perforations in patients without underlying esophageal pathology are most amenable to stenting. In a report of 17 such patients, leak occlusion occurred in 94% as confirmed by contrast esophagram.¹⁸ Of note, all patients underwent simultaneous endoscopic or surgical procedures, and 18% of patients required repeat endoscopy for replacement or repositioning due to stent migration. In our opinion, highly selected patients may be candidates for stenting but should be cared for by a thoracic surgeon and managed expectantly in case urgent surgical exploration is clinically mandated.

Operative Treatment. The operative management of esophageal perforation is dictated by the location of the perforation, the extent of injury, and the presence or absence of underlying esophageal pathology. Approaches include drainage alone, primary reinforced repair, esophagectomy with immediate reconstruction, and exclusion or resection with diversion.

Although the anatomic relationships of the neck and mediastinum had been previously described, Herman Pearse's 1938 publication¹⁹ regarding cervicomedial fascial continuity and the surgical prevention and management of mediastinitis following cervical suppuration was indeed landmark. Pearse noted that approximately 20 percent of cases of suppurative mediastinitis resulted from descending cervical infections, most as a result of cervical esophageal perforation. He identified the retrovisceral space as the most common path of dependent spread and advocated early operative drainage via cervical mediastinotomy in such cases, noting 35% mortality in patients operated on as compared to 85% mortality in the nonoperative group.¹⁹ Air within the retrovisceral space may be detected by lateral roentogram of the neck. The typical radiographic studies
